In the work, the peculiarities of formation of dissimilar joints of Ti–46Al–2Cr–2Nb alloy on the base of titanium aluminide γ-TiAl with titanium alloy VT5 in resistance butt welding, in particular, using interlayers in the form of nanolayer foils were studied. In resistance butt welding without the use of nanolayer foils it was failed to provide the defect-free joints: in the butts the presence of areas of cast metal and cracks was detected. It was found that the use of Ti/Cu and Cu–Ti/Ni–C systems as an interlayer of nanolayer foils of an eutectic type significantly influences the activation processes of the surfaces to be welded and the formation of joints in resistance butt welding. The presence of nanolayer foils in the contact zone facilitates the formation of a thin layer of the liquid phase at the initial stage of the heating process, localization of heat evolution process, activation of surfaces of both alloys with the duration of heating stage of 50–60 % of such at the direct resistance butt welding of alloys γ-TiAl and VT5. The two-stage pressure cycleogram provides formation of defect-free joints at the values of heating temperature, which are lower than those of the liquidus temperature in the system Ti–Al. According to the data of scanning electron microscopy and the EDS-analysis, the absence of the areas of cast metal and the remnants of nanolayer foils in the zone of joints was established, which testifies the solid-phase nature of the formation of joints and the complete displacement of nanolayer foils beyond the cross-section of the billets. 12 Ref., 8 Figures.

Keywords: titanium aluminide, VT5 alloy, resistance butt welding, nanolayer foil, solid-phase joint

The promising materials for production of components of aircraft and automobile engines are the intermetallic-based alloys, in particular, titanium aluminides [1–5]. Due to low specific weight and high heat resistance, titanium aluminides and the alloys based on them have advantages over the existing titanium and nickel alloys in a wide range of temperatures. The titanium aluminides are envisaged for using in manufacture of valves in automobile engines [2] and parts of aircraft engines operating at high temperatures [4].

One of the reasons that inhibits the use of intermetallic alloys is the complexity of their technological treatment, in particular, welding, predetermined by extremely low ductility at room temperature, high sensitivity to thermal and deformation cycles of treatment [6]. Perspective for the permanent joint of intermetallic alloys in similar and dissimilar combinations is the use of pressure welding methods [7–11], in particular, resistance butt welding (RBW) [10, 11]. The development of an effective technology for RBW of intermetallic alloys is associated with a number of problems, in particular, with a nonuniformity of heating and deformation processes of near-contact material volumes, considerable resistance to plastic deformation, high electrical resistance and a large temperature range of brittleness of these alloys.

An effective technological procedure, which facilitates the activation of welded surfaces and intensification of diffusion processes in the joint zone, is the use of intermediate layers. As such layers, nanolayer foils (NF) on the base of reaction elements which are the part of materials welded [9–11] can be used. To weld dissimilar materials, it is important to use intermediate layers that will, on the one hand, facilitate the establishment of physical contact and on the other hand, prevent the mixing of elements being a part of materials welded. To such requirements intermediate layers in the form of NF correspond, having a nonuniform distribution of structure parameters across the thickness.

The previous experience shows the effectiveness of applying NF as interlayers and activators in RBW of alloys based on titanium aluminides in a homogeneous combination. The positive effect of using NF is manifested in the localization of the processes of heat evolution and deformation in the contact zone, which facilitates the activation of surfaces welded and...
provides the formation of joints at essentially lower values of energy input [11].

The aim of investigations was to establish the peculiarities of formation of dissimilar joints of alloy on the base of γ-titanium aluminate with high-strength titanium alloy in RBW, i.e. directly and with the use of NF at a nonuniform distribution of structure parameters.

The influence of RBW modes on the formation of Ti–46Al–2Cr–2Nb (γ-TiAl) titanium aluminide joints with the alloy VT5 (hereinafter — joint γ-TiAl + VT5) was investigated. A comprehensive research methodology was developed, which included producing welded joints by different technological schemes: directly by RBW and RBW using NF of different chemical composition. To carry out investigations, the machine K766 was modernized to provide a high quick-response of compression mechanism and precision control of compression forces during the welding current passing. The range of technological parameters change was optimized based on previous experiments in such a way that to provide a predetermined value of upsetting during welding. The parameters of RBW mode were changed within the following limits: pressure at heating \( P = 2–10 \) MPa, pressure during upsetting of 10–50 MPa, welding time 1.5–3.5 s.

The structure of joints and presence of defects were determined by metallographic examinations of sections prepared using the chemical method of detecting the structure. An optical microscopy (Neo-phot-32), scanning microscopy (Auger-microprobe JAMP-9500F and scanning electron microscope JSM-35SA, JEOL), micro X-ray spectral analysis of elements distribution (EDS-analyzer INCA-450, Oxford Instruments), measurements of microhardness (M400, LECO, at loading of 1–5 N). The mechanical properties of joints were evaluated by the distribution of microhardness of metal in the zone of joint and in the zone of thermomechanical effect on the butts.

For conducting experiments on RBW with the use of intermediate layers, NF of system Ti/AI and foils with a nonuniform distribution of parameters of the structure of two types were selected: discrete (TiNb/Al, Ni/Ti–Al, Ti/Ni–Cu, Ni–Ti/Cu–Ni, Ti–Al/Ni–Ti, Al/Ni–Cu) and gradient (Cu/Ti). The thickness of NF was 30–60 μm, the thickness of each layer was 10–50 nm. The microstructure and the results of micro X-ray spectral analysis of NF Al/Ni–Cu, Cu/Ti and Cu–Ti/Ni–Cu across their thickness are presented in Figure 1.

An essential characteristic of the discrete type of foils, used as an intermediate layer in RBW is the material of outer layers. According to the research methodology, it was envisaged that the use of NF of a discrete type with an outer layer having thermophysical characteristics different from those of alloys welded should have a significant influence on heating, deformation processes, character and intensity of diffusion processes in the contact zone during welding.

Thus, for the NF of Ti–Al/Ni–Ti the outer layer (titanium) corresponded to the base of both alloys welded; for the NF of Cu–Ti/Ni–Cu and Ni–Al/Ni–Ni, the outer layers (copper and nickel) form the low-melting eutectic with the base of both alloys. It was envisaged that during metallographic examinations of the joints, the difference in detection of the NF structure and the base metal of alloys would allow establishing the regularities of behavior of the near-contact volumes of metal and material of the interlayer in the process of welding.

The influence of RBW modes in a wide range of changes in technological parameters on the formation of γ-TiAl + VT5 joints was investigated. The structure of the joint zone produced by RBW at the optimal mode without the use of intermediate layers is shown in Figure 2, a, b, respectively, in the central and peripheral parts of the section of billets. The presence of areas of cast metal and microcracks in the joint zone is noted.

The analysis of the results of oscillography of the value of welding current and the measurement of temperature by thermocouples indicate that, in this case, during RBW process, the formation of the joint occurred through a melt layer which solidified after the stage of deformation of billets in the cooling process. During RBW without melting directly, it was not possible to form joining of the alloys γ-TiAl + VT5, as the defects of the type of oxide films and lacks of penetration were detected.
The influence of RBW modes on the structure of joints of γ-TiAl + VT5 alloys produced through NF of Ti/Al system was investigated. The temperature-time parameters of the welding process provided exceeding the melting temperature of the alloys γ-TiAl (\(T_{\text{liquidus}} = 1475 ^\circ C\)) and VT5 (\(T_{\text{liquidus}} = 1670 ^\circ C\)) in the contact zone according to the state diagram of the Ti–Al system (Figure 3) [12]. In this case, the axial force at the stage of upsetting was not increased (single-stage pressure cyclogram). It was established that during air cooling of γ-TiAl + VT5 joints produced by RBW with a single-stage pressure cyclogram, the cracks are formed in welded butts directly throughout the diffusion zone or in the areas of the γ-TiAl alloy adjacent to it (Figure 4, a), obviously, due to structural transformations «melt \(\rightarrow\) α-phase \(\rightarrow\) (\(\alpha_2 + \gamma\))», which are accompanied by the appearance of significant welding stresses.

The structure of joints of alloys γ-TiAl + VT5, produced by RBW through the NF of Ti/Al system with a two-stage pressure cyclogram, was investigated when the melting temperature of the alloy γ-TiAl was reached in the contact zone. During the analysis of the joint microstructure, the formation of common grains at the contact boundary of the alloys γ-TiAl + VT5 (Figure 4, b) is observed.

Obviously, in the process of heating during RBW, a short-term local achievement of the liquidus temperature of alloys was provided, at the same time the melt areas were solidified at the stage of deformation of billets during upsetting. In this case, the solid-phase nature of the formation of the joint γ-TiAl + VT5 in the \(\alpha\)-region of the state diagram of the Ti-Al system was provided. The registration of thermal cycles with the help of thermocouples established that the use of NF provides localization of heat evolution in the contact area (along the axis of billets) and a more uniform heat evolution across the section of billets as compared to RBW without the use of NF.

The oxide films, pores, cracks and other defects in the joining zone were not revealed. The analysis of microstructure of joint shows the presence of a diffusion zone with a width of more than 100 \(\mu m\), in which the content of titanium gradually decreases from about 93 \(\text{g}, \text{at.}\%\) in the alloy VT5 to 50 \(\text{at.}\%\) in the alloy of γ-TiAl, which, in accordance with the
state diagram of the system Ti–Al, predetermines the existence of several phases of different composition — α(Ti), α + α2, α(Ti)Al, α2 + γ (TiAl). The nature of change of microhardness in the zone of joining of γ-TiAl + VT5 (Figure 5) indicates the absence of areas with decreased strength in the heat-affected zone of both alloys. The presence of a wide diffusion zone is a significant factor which can affect mechanical characteristics of welded butts, in particular, the formation of cracks during their heat treatment or operational loads.

The influence of RBW modes on the structure of joints γ-TiAl + VT5 produced with the use of NF of eutectic type with a nonuniform distribution of the structure parameters across the thickness: discrete (Ni/Ti–Al, Ti/Ni–Cu, Cu–Ti/Ni–Cu, Al/Ni–Cu) and gradient (Ti/Al, Cu/Ti). The technological parameters of the RBW mode were set so, that to provide a short-term eutectic temperature exceeding in the

titanium-material of external NF layer system in the contact zone.

In particular, for NF of the system Cu–Ti/Ni–Cu and Cu/Ti the heating temperature during RBW process should exceed the value of $T_{\text{eutCu–Ti}} = 885 \degree C$ for a short time in accordance with the state diagram of the system Cu–Ti [12]. At the same time, the temperature-time conditions of the RBW process (value
of voltage, current, time, heating pressure, upsetting pressure) were controlled in such a way that to prevent exceeding the melting temperature of alloy γ-TiAl in the contact zone (Figure 6). The process of forming the joint occurs in α-region or (α + γ) region according to the state diagram of Ti–Al system.

The experiments showed that the optimal conditions for formation of joints in RBW are provided with the use of NF of systems Cu–Ti/Ni–Cu and Cu/Ti. The microstructure of joint γ-TiAl + VT5 at scanning electron microscopy (SEM) and the results of micro X-ray spectral analysis are presented in Figures 7, 8.

It was established that the use of NF significantly influences the processes of activation of surfaces welded and the formation of joints. The use of the systems Cu–Ti/Ni–Cu and Cu/Ti in RBW with a two-stage pressure cyclogram facilitates the formation of a thin layer of liquid phase at the initial stage of heating process, localization of heat evolution process, the activation of surfaces of both alloys and the formation of defect-free joints at the stage of upsetting with the duration of heating stage being 50–60 % of such at the direct RBW. With the help of SEM (Auger-microprobe JAMP-9500F, JEOL EDS-analyzer INCA-450), the absence of areas of cast metal, NF remnants was established in the joints zone, which proves the solid-phase nature of formation of joints and the complete displacement of NF beyond the boundaries of the cross-section of billets. The width of the diffusion zone in the joint γ-TiAl + VT5 does not exceed 50 μm (Figure 8).

Conclusions

1. In resistance butt welding (RBW) of the alloy γ-TiAl with titanium alloy VT5 without the use of intermediate layers it was not possible to provide defect-free joints: the presence of areas of cast metal and cracks was recorded in the butts. The formation of joints occurred through a melt layer, which solidified after the stage of deformation of billets during cooling of the butts.

2. In the butts produced by RBW through the NF of the Ti/Al system at a single-stage pressure cyclogram, the cracks are formed directly across the diffusion zone or in the areas of the alloy γ-TiAl adjacent to it apparently, due to the structural transformations melt → α-phase → (α + γ) → (α_n + γ), which are accompanied by the appearance of significant welding stresses.

3. Two-stage pressure cyclogram in RBW through the NF of the Ti/Al system provides the formation of defect-free joints. The presence of a diffusion zone with a width of more than 100 μm is a significant factor that can affect the mechanical characteristics of welded butts, in particular, the formation of cracks during their heat treatment or operating loads.

4. The use of the eutectic type of the Ti/Cu and Cu–Ti/Ni–Cu systems as an intermediate layer of NF significantly affects the activation processes of welded surfaces and formation of joints in RBW. The presence of NF in the contact zone results in the formation of a thin layer of liquid phase at the initial stage of heating process, localization of heat evolution process, activation of surfaces of both alloys at the duration of heating stage of 50–60 % of such at direct RBW of alloys γ-TiAl and VT5.

5. In RBW with a two-stage pressure cyclogram, the formation of defect-free joints is provided at the values of heating temperature lower than the liquidus temperature in the Ti–Al system. According to the data of micro X-ray spectral analysis, the absence of the areas of cast metal and the NF remnants was established, which testifies the solid-phase nature of the formation of joints and the complete displacement of NF beyond the cross-section of the billets.
EFFECT OF PULSED-ARC WELDING MODES ON THE CHANGE OF WELD METAL AND HAZ PARAMETERS OF WELDED JOINTS PRODUCED WITH Sv-08Kh20N9G7T WIRE

Pulsed-arc welding is characterized by periodically varying arc power and due to its peculiarities it allows solving complex technology issues in development of unique structures, increasing the efficiency of welding processes, and depositing corrosion-resistant alloys on steel. At present, there is a great number of welding equipment manufacturers, who have introduced the ideas of pulsed welding application in their production. However, the data on the effect of pulsed-arc welding on the welding thermal cycles are of a fragmentary nature, and, therefore, it is difficult to compare the thermal cycles typical for stationary and pulsed-arc welding. In welding of high-carbon steels there is a problem of reducing weld metal mixing with base metal and the resulting increase of welded joint cold cracking resistance. Successful application of pulsed-arc welding for solution of the above-mentioned problems necessitated performance of comparative investigations of the effect of the modes of pulsed-arc welding on the parameters of welds, HAZ and welding thermal cycles in comparison with stationary arc welding produced with high-alloy welding consumables. This was the main aim of the investigations, the results of which are given in this paper. 31 Ref., 8 Figures.

Keywords: pulsed-arc welding, pulsating-arc welding, welding thermal cycle, heat-affected zone, high-alloy welding consumables

Pulsed-arc welding (PAW) is characterized by periodically changed power of the arc, and it has been known since 1940s. Welding process with periodically changed arc power was proposed for the first time in the USSR in 1953 by Zajtsev M.P., for welding steel sheets, in order to reduce the heat losses [1]. However, the first mention of pulsed welding in the world dates back to 1932. This kind of welding was invented by engineer Earl J. Ragsdale in Budd Company in 1932 for stainless steel welding and was used to manufacture diesel railway train Pioneer Zephyr [2]. Pulsed-arc welding in this case allowed 3–8 times increase of labour efficiency, compared to nonconsumable electrode welding, and considerable reduction of deformation during its performance at practically the same quality of welded joints. Different authors called welding with periodically changing power of the arc in different ways: pulsed-arc, pulsating-arc, modulated current, and nonstationary arc welding. However, the common name of all the above methods is modulated current welding (MCW) [3]. MCW mainly allows ensuring a controllable transfer of electrode metal, increasing arcing stability, reducing spatter, as well as controlling the rate and direction of weld pool metal solidification, regulating the thermal impact on the heat-affected zone (HAZ) of welded joints. By pulse repetition rate MCW is divided into PAW (f ≥ 25 Hz, Figure 1, a) and pulsating-arc welding (f < 25 Hz, Figure 1, b).

PAW [4–6] provides controllable transfer of electrode metal, the main condition of which is drop detachment by each current pulse and possibility of controlling their transfer frequency. It is believed that in gas-shielded welding, the pulse duration should be sufficient for detachment of the electrode metal drop. In the case of drop detachment at the current close to the amplitude value, metal transfer is accompanied by greater spatter [7]. Minimum spattering losses and controlled metal transfer at welding in all the positions ensure drop detachment at the end of pulse action. The main advantages of PAW include its ability to be used for critical structures from different steel grades, aluminium, copper, nickel alloys and titanium of 1 mm and greater thickness.

Owing to high spatial stabilization of the arc and possibility of application of greater electrode extension, this process can be used with success, both for welding thin metal, and for thick-walled structures. PAW in an intermediate link between spray transfer and short arc welding that makes it ideal for weld-
PAW, owing to its features, allows solving complex technological issues at development of unique structures, increasing the efficiency of the welding process and depositing corrosion-resistant alloys on steel [8]. At present there exists a great number of welding equipment manufacturers, who introduced the ideas of pulsed welding application in their production. Swedish Company ESAB developed Aristo 500 power source for PAW [9] with program control, which automatically assigns the welding modes, according to synergistic dependencies. US Company Hobart developed Ultra-Arc 350 system for consumable electrode PAW [10]. This system has nine programs, envisaging welding of carbon and stainless steels in a mixture of gases with 0.8 and 1.2 mm wires. PWI developed I-169 power source for PAW with smooth regulation of the parameters of current pulses of a stepped form [11].

An important condition of the stationary nature of running of PAW process is the optimum combination of the pulse and pause parameters [8, 12–19]. In view of the fact that the number of variable parameters at PAW is considerable, selection of their optimum combination is a quite labour-consuming process and it includes a large number of trials and errors [20]. General recommendation for selection of an optimum combination of PAW parameters is transfer of one drop per pulse [8, 12]. This condition, which is the criterion of metal transfer, can be expressed by the following relationship [12, 21]:

$$D = \frac{I_p}{I_{\text{pause}}}$$

where \(D\) is the constant, depending on drop volume, welding wire composition and diameter; exponent \(\alpha\) has the average value of 2.

If values \(I_p/I_{\text{pause}}\) are small, then the energy of one pulse is insufficient for drop detachment. In this case, the drop can separate from the electrode under the impact of gravitation forces. In the case, when the products of pulse current and time have large values, two or three drops can separate per one pulse, and the stability of the welding process is disturbed. Minimum pause current is selected so that the arc was not extinguished during the pause. Modern power sources use the above-listed recommendations for PAW in the programmed modes. As a rule, operator instrument panels show average values of current, which is determined by the following equation [8, 12, 22]:

$$I_{\text{av}} = \frac{I_p t_p + I_{\text{pause}} t_{\text{pause}}}{t_p + t_{\text{pause}}}$$

In this case, it is possible to compare PAW modes with those of stationary welding, welding heat input is directly proportional to welding current.

One of the most important characteristics, determining the welded joint properties, is the welding thermal cycle (WTC), which determines the HAZ metal structure. Knowing the features of WTC at pulsed-arc welding mode it is possible to predict formation of the structure and properties of welded joint HAZ. So, for instance the authors of [12, 23–25] report that PAW is characterized by a lower level of heat input, thus ensuring penetration comparable with spray transfer. K. Tsen [26], measuring the welding thermal cycles for the stationary and pulsating modes, at 2 mm distance from the fusion line, showed that in the latter case smaller maximum temperature of metal heating is achieved. This fact can be an indication, in the opinion of the authors of [26], of smaller heat input. As the metal heating temperature is smaller in the case of the pulsed process at the same distance from the fusion line, this leads to an indirect conclusion that the HAZ width in this case was smaller, and that the rate of metal cooling in the high-temperature region was higher, compared to the process, which was performed by a stationary arc. The effect of the pulse repetition rate and fullness on the metal cooling rate is considered in [27]. It is shown that in the range of the change of repetition rate from 60 up to 120 Hz and of fullness from 20 up to 30 %, the cooling rate practically does not change, either in the high-tem-

![Figure 1. Change of current in time at PAW (f ≥ 25 Hz) (a) and pulsating-arc welding (f < 25 Hz) (b): tp — pulse time; tpause — pause time; t — current rise time; td — current drop time; Ip — pulse current; Ipause — pause current](image-url)
perature, or in the low-temperature regions. Values of pulse repetition rates and fullness were selected, proceeding from the fact that these ranges of PAW parameters cover a wide area of practical application [28]. It should be also noted that based on WTC data for the pulsed mode, a certain «tooth» (jump) in metal temperature variation is observed in the high-temperature region that, in all probability, is attributable to the features of pulsed heat input into the weld pool. Study of WTC in the case of pulsating-arc welding [22, 29] showed that in the low-temperature range the rate of HAZ metal cooling is slowed down, compared to the stationary mode, and in the high-temperature range it is accelerated. Here, in the case [29] of arc pulsation frequency rising from 0.5 up to 10 Hz, the rate of HAZ metal cooling becomes the same, as in the case of stationary welding, that is indicative of irrationality of further increase of pulsation frequency.

It should be also noted that the data on PAW effect on the welding thermal cycles are of a fragmentary nature and, therefore, it is difficult to make a comparison between the thermal cycles, characteristic for welding by a steadily burning and pulsed arc. A similar situation is observed in investigations, dealing with variation of weld parameters [30, 31]. The works mainly give comparison of weld parameters at different variants of pulsed or pulsating welding, whereas comparison with similar results for stationary arc welding is absent. Such data are required for understanding the conditions, under which stationary arc welding can be replaced by PAW, in order to increase the productivity and improve product quality. For performing tasks such as welding of high-strength fine-grained steels, it was necessary to solve two mutually exclusive problems of improvement of the process productivity and ensuring the fine-grained structure in the HAZ metal, as well as good penetration of the weld root. Moreover, in welding high-carbon steels, the problem arises of reducing weld metal mixing with base metal and this way increasing welded joint resistance to cold cracking. Thus, successful application of PAW in solving the above problems necessitated performance of comparative studies of the influence of PAW modes on the parameters of welds (width, reinforcement height, penetration depth), HAZ and WTC, compared to stationary arc, performed earlier by high-alloy welding consumables. This was the main purpose of investigations, the results of which are given in this paper.

Experimental procedure. In order to solve the problem defined in the work, beads were deposited by HORDA 307Ti high-alloyed welding wire, which is an analog of the known wire of Sv-08Kh20N19G7T grade. Wire of 1.2 mm diameter was used. Deposition was performed on 10 mm plates from 09G2S steel. Plates with the deposited bead were used to prepare sections for performing measurements of weld and HAZ parameters. To reveal the HAZ, the sections were subjected to macroetching by a solution of ferric chloride. WTC of the HAZ overheated zone was recorded, using chromel-alumel thermocouples of 0.5 mm diameter. The thermocouple was mounted in the HAZ area, which was heated up to the temperature of 1200 °C.

To assess the effect of PAW modes on weld parameters the following modes were selected: welding current $I = 120, 160, 200, 240$ A, voltage $U = 20, 24, 28, 30$ V, welding speed of $15$ m/h, shielding gas — a mixture of Ar + 18% CO₂. Inverter type rectifier of ewm Phoenix Pulse 401 grade was used as the current source, which provides pulse repetition rate of 130 Hz at PAW.

Optimum pulsation modes were selected using a pulsating arc. In this case the welding mode was as follows: pulse welding current $I_p = 160$ A, pause current (base current) $I_{\text{pause}} = 80$ A; arc voltage in the pulse $U_p = 24$ V, arc voltage in the pause $U_{\text{pause}} = 18$ V; $v_s = 15$ m/h. Pulse time $t_p$ and pause time $t_{\text{pause}}$ as well as pause current and pulse-to-pause ratio were varied. Values of pause current were as follows: $I_{\text{pause}} = 60, 80, 100, 120$ A; pulse-to-pause ratio was varied from 1.4 to 2.0, pulse repetition rate was higher than 0.5 Hz.

Results and their discussion. Pulsed-arc welding. Appearance of bead deposits, made by stationary welding and PAW, is given in Figure 2. At comparison of stationary and pulsed-arc welding modes one can clearly see, that at PAW the weld bead is more uniform and regular without traces of spattering (Figure 2, b). Measurements of metal losses for spatter showed that at PAW it is reduced by an order of magnitude, from 0.7% at stationary mode to 0.07% at PAW.

Analysis of the cross-section of the beads deposited in different modes, revealed that the penetration depth at PAW becomes greater, compared to stationary welding in the same modes (Figure 3). The shape of weld penetration at PAW differs significantly from
the process, which was performed by stationary arc. Quantitative analysis showed that the weld width also becomes greater with increase of welding current. The nature of variation of this value is the same, both for welding by a stationary arc, and for PAW. A similar dependence is also observed for weld height. As regards penetration depth, on the whole, it increases with increase of welding current, but in the case of PAW the penetration depth is practically two times greater than in the case of stationary arc welding (Figure 4, a). At PAW also the weld cross-sectional area exceeds these values for stationary arc welding. HAZ value under the cap is comparable for both kinds of welding, and in the weld root the HAZ is smaller at PAW (Figure 4, b). Another important parameter is the width of the HAZ at weld surface, the values of which in PAW at currents higher than 160 A become smaller than in stationary arc welding.

**Pulsating-arc welding.** At pulse frequency of 0.3 Hz coarse-flaky intermittent weld forms (Figure 5), where the uniformity of bead width along weld length increases with pulse-to-pause ratio reduction. At small frequency of arc pulsations also a nonuniform penetration of the plate is observed (i.e. a marked change of penetration depth along the weld length is found, which reaches 70 %, Figure 5, b). Penetration uniformity can be increased by increasing the arc pulsation frequency up to 1 Hz. At constant values of

![Image](image_url)

**Figure 3.** Appearance of the deposits, made by stationary-arc welding (a) and PAW (b) at the speed of 15 m/h; transverse macrosections

![Image](image_url)

**Figure 4.** Change of weld and HAZ parameters at stationary-arc welding (1) and PAW (2), welding speed of 15 m/h: a — penetration depth; b — HAZ width in weld root

![Image](image_url)

**Figure 5.** Appearance of deposited bead in the mode of pulsating-arc welding with pulse repetition rate of 0.3 Hz (I_p = 160 A, pulse voltage U_p = 24 V; I_pause = 80 A; U_pause = 18 V); a — top view; b — longitudinal section
average current and process pulse-to-pause ratio, also the uniformity of weld bead formation is improved and flakiness becomes smaller with increase of arc pulsation frequency.

Experimental data show that with increase of pause current the weld width first somewhat decreases, and then increases, smaller values of pulse-to-pause ratio corresponding to greater weld width (Figure 6, a). Weld height increases uniformly with increase of pause current. Change of penetration depth has some features. At pulse-to-pause ratio equal to two, it changes from 1 mm (that corresponds to penetration depth at stationary welding mode at specified current) up to 1.8 mm. At smaller pulse-to-pause ratio (1.4 and 1.5) the values of penetration depth are in the range of 1.7 mm that is by 70 % greater than in the stationary mode. Weld area increases accordingly with increase of pause current.

Change of HAZ parameters under the cap is of a monotonic nature. Smaller pulse-to-pause ratio corresponds to greater values of HAZ width. It is important to note that average HAZ values under the cap are lower than in stationary arc welding and PAW. Similar regularities are observed also for HAZ, both in the weld root (Figure 6, b) and at the weld surface. With increase of pause current the angle of transition to base metal decreases for pulse-to-pause ratio of 2, and practically does not change for smaller values.

In the welding mode with pulse current $I_p = 160$ A and pause current $I_{\text{pause}} = 120$ A (fixed pulse time of 0.5 s) with greater pause time, weld height increases, weld width becomes somewhat smaller, and HAZ width decreases, while penetration depth practically does not change. In the case of fixation of pause time (0.5 s) and increase of pulse time, weld height decreases, and weld width increases (that is, apparently, associated with increase of penetrability/effectiveness). HAZ width changes nonlinearly, first increasing, then decreasing and increasing again.

Analysis of welding thermal cycles allowed establishing the following features: at PAW the rate of rise of metal temperature in the HAZ overheated zone is greater than in the case of stationary-arc welding; in the high-temperature region from 1350 to 1000 °C metal cooling at PAW occurs faster, and in the region...
of temperatures below 1000 °C it proceeds slower (Figure 7). More detailed analysis of the effect of pulsed welding mode on the rate of metal cooling in the HAZ is given in Figure 8. The given data show that the rate of metal cooling in the range of temperatures of the lowest austenite stability of 600–500 °C is lower for PAW, than in the case of stationary-arc welding, whereas time $\tau_{\text{H}}$ has close values.

Changes of cooling conditions, observed at transition from stationary-arc welding to PAW suggest that in this welding process a more favourable structure with a higher cold cracking and brittle fracture resistance will form in the metal of HAZ of high-strength steels with $\sigma_{0.2} > 600$ MPa. Work in this direction will be the result of out further studies.

Conclusions

1. Pulsed-arc welding allows reducing metal spattering, HAZ width, and increasing penetration depth (practically 2 times) compared to stationary arc welding. Rate of metal cooling in the HAZ in the temperature range of 600–500 °C is here reduced practically 1.5 times.

2. Application of pulsating-arc welding allows increasing weld width and reducing HAZ width, compared to stationary-arc welding.

3. Processes of pulsed-arc welding and pulsating-arc welding feature greater capabilities for controlling the weld parameters and heat input.

A series of research was performed to study the characteristics of structural strength of butt joints of aluminium alloy D16T 2 mm thick, produced by friction stir welding. Features of weld formation and degree of metal softening in the zone of the produced permanent joint were analyzed. Mechanical testing of welded joint samples was performed at static and cyclic loading. Diagrams of fatigue crack growth rates in the base metal, heat-affected zone and thermomechanical impact zone, on the boundary of these zones and in the weld metal were plotted. It is shown that the characteristics of cyclic crack resistance of weld metal of these joints are more than two times higher than the respective values for base metal that is indicative of the good prospects for application of friction stir welding in fabrication of critical structures from D16T alloy. 19 Ref., 8 Figures.

Keywords: aluminium alloy D16T, friction stir welding, microstructure, cyclic crack resistance, structural strength

Aluminium alloys of different alloying systems are widely applied in aerospace engineering [1, 2]. This is due to a combination of low metal content of aluminium alloys and quite high values of strength and crack resistance that together provide a reliable and long-term operation of metal structure assemblies [3]. Under the conditions of cyclic loading, the structural strength [4] is evaluated by complex parameter \[ \sigma_s - D_K \], where \( \sigma_s \) is the material ultimate strength, as well as the values of material cyclic crack resistance: \( D_K^{th} \) is the fatigue threshold; \( D_K^{fc} \) is the cyclic fracture toughness [5]. These parameters are particularly important at operation of structures by the fail-safe concept [6].

In fabrication of aerospace engineering components various methods of welding these aluminium alloys are used to produce permanent joints. Here, certain problems often arise due both to chemical composition of the aluminium alloys being welded, and to the welding process, which lead to lowering of welded joint structural strength. In particular, this is metal softening in the permanent joint zone [7], and formation of cast coarse-grained structure of welds [8], and appearance of characteristic defects in the form of pores, oxide film macroinclusions and hot solidification cracks [9–11]. Therefore, the available welding technologies are optimized, and new methods to produce permanent joints are developed, in order to improve the performance of aluminium alloy components.

The method of friction stir welding (FSW) is considered to be one of the most promising in fabrication of critical structures, including aerospace engineering. It was developed in 1991 at The Welding Institute as a method to produce joints in the solid phase [12]. FSW process has a characteristic difference from other pressure welding processes, due, mainly, to application of a special welding tool (Figure 1). Therefore, the main stages of permanent joint formation are directly related to this tool. Metal heating up to the plastic state, as well as prior cleaning of the surfaces of edges to be welded from oxide film, as a result of their friction with the shoulder working surface, take

![Figure 1. Schematic of FSW process: 1 — tool shoulder; 2 — tool pin; 3 — weld; 4 — welded blanks](image-url)
place under the tool shoulder. Owing to slight immersion of the tool into the metal being welded and its inclination relative to the vertical axis, the metal is in constant contact with the shoulder leading edge, forming a wave of plasticized metal owing welded. Mixing across the entire thickness occurs due to rotation of the tool pin. Metal heated up to the plastic state due to high adhesion of aluminium, is entrained by the pin side surface and is plastically deformed, moving after it. It results in intensive mass transfer of the metal being welded, at which the edges being welded are cleaned from oxide films and come into contact. Owing to intensive plastic deformation and heating, the metal goes into the plastic state, and its grains in the zone of direct impact of the tool are refined significantly that additionally promotes its viscoplastic flow. Under the shoulder rear edge, owing to tool inclination in the vertical plane, conditions are in place for additional compression of metal, moved into this zone by the pin working surfaces, substrate and the metal being welded proper.

Thermomechanical conditions, at which permanent joints form in FSW result in a specific weld structure (Figure 2). Unlike welds of a cast structure, characteristic for fusion welding processes, they have fine deformed structure, with a clear-cut nugget $D$ formed as a result of dynamic recrystallization, with up to 10 $\mu$m grain size. Bending, elongation and partial recrystallization of the grains proceed in the thermomechanical impact zone (TMIZ) $C$, adjacent to the nugget, as here the metal is subjected to heating and plastic deformation. Behind this area is the HAZ $B$, in which the metal remains undeformed and changes its structure only as a result of temperature rise. Next comes base metal zone $A$, where the metal does not undergo any changes [13, 14].

The objective of this work is evaluation of strength characteristics and cyclic crack resistance of welded joints of D16T alloy 2 mm thick, produced by FSW.

**Experimental procedure.** Investigations were conducted on butt joints of D16T alloy sheets (wt. %: 4.5 Cu; 1.7 Mg; 0.53 Mn; 0.19 Si; 0.21 Fe; 0.11 Zr; 0.06 Ti; bal. — Al); welded along the rolling direction. Ultimate strength of this alloy sheets in the state after hardening and natural ageing $\sigma_t = 445$ MPa, and relative elongation $\delta = 11$%. FSW process was performed in a laboratory unit developed at PWI. The rate of rotation of special welding tool [15] with a conical pin and 12 mm dia shoulder was 1420 rpm, and the speed of its linear displacement (welding speed) was 10 m/h.

Investigations were conducted in different zones of the welded joint (see Figure 2): in the weld central part (nugget), on the boundary of thermomechanical impact and heat-affected zones, in TMIZ and HAZ at 1 mm distance from this boundary, as well as in the base metal. These areas were selected in the characteristic points of change of local values of metal specific electric conductivity (Figure 3, points $a$–$f$), which is the physical characteristic of aluminium alloys, sensitive to the change of their structure and local stress-strain state, occurring during welding [3]. Values of specific electric conductivity were measured, using the eddy current method, with 1 mm step at alternating current frequency of 100 kHz that ensured the control depth up to 2 mm [16].

Metal hardness was measured on face surfaces of the produced welded joints. Degree of metal softening in the welding zone was assessed in ROCKWELL instrument at the load $P = 600$ N. Evaluation of structural features of welded joints was performed in MIM-8 optical electronic microscope. Ultimate strength of welded joints $\sigma^{w,j}$ and weld metal $\sigma^{w,m}$ was determined on standard samples with test portion width of 15 mm. Characteristics of cyclic crack resistance were determined on samples-strips 30 mm wide with side sharp (0.1 mm radius) U-shaped notch 2 mm deep along the axis of the studied zone of the welded joint, in keeping with the procedure, accepted
by ASTM International [17]. Obtained experimental data were the basis to plot the diagrams of fatigue macrocrack growth rates — \( da/dN - \Delta K \) dependencies at the frequency of 10–12 Hz and coefficient of asymmetry \( R = 0.1 \) of the loading cycle in atmosphere at room (20 °C) temperature. Crack length was measured by cathetometer KM-6 at 25-fold magnification with 0.02 mm error. Obtained results were described by the respective analytical dependencies:

\[
d{a \over dN} = C_1(\Delta K - \Delta K_{th})^{n_1}, \text{ if } 10^{-10} \leq {d{a \over dN}} \leq 10^{-8}, \text{ m/cycle}; (1)
\]

\[
d{a \over dN} = C_2(\Delta K)^{n_2}, \text{ if } 10^{-8} \leq {d{a \over dN}} \leq 10^{-5}, \text{ m/cycle}, \quad (2)
\]

where \( da \) is the increment of crack length between the two successive measurements; \( dN \) is the number of loading cycles between two successive measurements; \( n_1, n_2 \) is the exponent determined in keeping with the procedure of [17].

Diagrams of fatigue macrocrack growth rates were shown by lines, corresponding to these dependencies. The parameters selected as cyclic crack resistance characteristics were fatigue threshold \( \Delta K_{th} \) and cyclic fracture toughness \( \Delta K_c = \Delta K_{th}^{10} \) and the ranges of stress intensity factors \( \Delta K \) at the crack growth rate \( {d{a \over dN}} = 10^{-10}, \text{ m/cycle and } 10^{-5}, \text{ m/cycle} \), respectively. Microfractographic features of fatigue fracture of samples were studied in a scanning electron microscope ZeissEVO-40XPV.

**Investigation results and discussion.** Performed investigations showed that the weld shape and dimensions in friction stir welding differ favourably from the weld produced by nonconsumable electrode argon-arc welding (GTAW) due to weld formation on a backing without the forming groove and producing a permanent joint without filler wire application (Figure 4). Absence of reinforcement or complete penetration in it allows avoiding high levels of stress concentration in the points of weld to base metal transition, adversely affecting the performance and life characteristics of welded joints.

In addition, permanent joint formation in the solid phase without base material melting prevents appearance of characteristic defects arising in fusion welding of aluminium alloys. So, absence of molten metal, in which hydrogen solubility increases markedly, allows avoiding additional saturation of the welding zone by it, because of migration of this gas from the adjacent metal layers and pore formation. Now, deformation and intensive stirring of plasticized metal over the entire thickness of the edges during welding, promoted fragmentation of oxide films present in them. Absence of molten metal in the zone of permanent joint formation allows avoiding its oxidation during welding. Therefore, welds, obtained by friction stir welding have no defects in the form of oxide film macroinclusions, appearing in GTAW. The most hazardous and inadmissible defects for critical structures are hot cracks, forming during molten metal solidification in the point of accumulation of low-melting eutectic inclusions. As in friction stir welding the weld forms in the solid phase, and processes of metal melting and solidification are absent, formation of such defects can be completely avoided.

Features of weld formation in friction stir welding also have a favourable effect on the degree of metal softening in the zone of permanent joint formation. So, metal hardness measurements in the zone of permanent joint formation showed that in friction stir welding of D16T alloy, weld metal hardness practically is on the level of base metal (Figure 5). In the thermomechanical impact zone metal hardness gradually decreases at greater distance from the weld, reaching minimum value (HRB 97–98) at the boundary of the thermomechanical impact and heat-affected zones that corresponds to the point of lowering of specific electric conductivity (see Figure 3). Therefore, at uniaxial static tension samples of friction-stir welded joints have a high (425 MPa) yield limit and fail near the boundary of abutment of the thermomechanical impact zone to the heat-affected zone, where the metal hardness is minimum.

![Figure 4. Transverse sections of welds of 2 mm alloy D16T produced by friction stir (a) and TIG welding (b)](image)

![Figure 5. Hardness distribution in welded joints of D16T alloy 2 mm thick, produced by FSW](image)
Investigation of the microstructure of welds showed that dynamic recrystallization of metal in the zone of intensive plastic deformation results in formation in the weld metal of a dispersed equilibrium structure with element size of 1–10 μm with individual intermetallics of 20–25 μm size, grouped into a conglomerate of grains of 70–150 μm size (Figure 6). Investigations of cyclic crack resistance revealed obvious differences in the diagram of the rate of fatigue macrocrack growth in the weld metal (Figure 7, curve 1), for which after intensive bulk plastic shear deformation the mid-amplitude traditionally straight Paris section is transformed into the curvilinear section with the inflection point at $\Delta K = \Delta K_0 = 20 \text{ MPa}\sqrt{\text{m}}$. This is characteristic exactly for the structure of the metal of weld, produced as a result of intensive plastic deformation of metal at FSW. Calculation of the size of cyclic plastic zone $r_p^c$ by the following formula:

$$r_p^c = 1/8\pi(\Delta K / \sigma_{0.2})^2,$$

where $\Delta K = 20 \text{ MPa}\sqrt{\text{m}}$, and yield limit $\sigma_{0.2} = 340 \text{ MPa}$, gives value $r_p^c = 138 \mu\text{m}$, that is in agreement with grain size (70–150 μm) of weld metal deformed during FSW. Thus, the inflection on the curve is indicative of the change of fracture mode, when at the tip of the fatigue macrocrack plastic deformation runs as multiplane dislocation slip in the volume of not one, but of several grains with involvement of grain-boundary processes. It can be also assumed that in such a deformed structure compressive residual stresses can arise [18], causing a considerable effect of crack tip closing. As a result, such weld metal, compared to base metal, demonstrates a higher fatigue threshold $\Delta K_{th}$ and cyclic fracture toughness $\Delta K_{fc}$ and, particularly, cyclic crack resistance index in mid-amplitude section of the diagram (Figure 7). Here, cyclic crack resistance of TMIZ and HAZ is somewhat lower, compared to weld metal: slightly in near-threshold section of the diagram and more in the mid- and high-amplitude sections (curves 2–4). For instance, the fatigue macrocrack growth rate at medium $\Delta K$ ranges can be by an order of magnitude higher than this value for weld metal. HAZ metal has the lowest cyclic crack resistance among all the welded joint zones (curve 3), although it is somewhat higher, compared to crack resistance of base metal, cut out across the rolling direction (curve 5), particularly in near-threshold and mid-amplitude sections of the diagram. Here, crack resistance of TMIZ metal (curve 2) is practically not inferior to crack resistance of base metal, cut out along the rolling direction (curve 6). In the high-amplitude section of the diagram, crack resistance index (cyclic fracture toughness $\Delta K_{fc}$) of HAZ metal is much lower, compared to base metal, cut out across the rolling direction. Therefore, further on it is rational to study the possibility of its increase by changing the structural components of HAZ metal and its stress-strain state by postweld heat treatment of such joints [19].

Analysis of microfractographs of tested sample fractures is indicative of the fact that the micromechanism of fatigue crack growth in all the studied...
zones of welded joints, produced by FSW, mainly is high-energy intensive pit one. Morphology of the pits and deformation ridges in weld metal fracture is the most finely-dispersed — individual fine cleavage sections (10–20 µm) are commensurate with weld structural elements (Figure 8, a). In TMIZ the number of sections of cleavage as a result of the impact of cyclic loads becomes greater, but they are divided by relatively large zones with deformation ridges (Figure 8, b), the most pronounced at the boundary of TMIZ and HAZ (Figure 8, c). Metal fracture morphology in the HAZ section is characterized by reduction of the number of extended deformation ridges and increase of the size of quasi-cleavage facets compared to weld metal (Figure 8, d), that, probably, is the reason for lowering of cyclic crack resistance index in this zone.

Conclusions

1. The process of friction stir welding allows producing sound welded joints of D16T alloy with high values of static strength that is just by 4–5% smaller than the respective values of base metal.

2. High values of strength of such joints are achieved due to lowering of the level of stress concentration in the points of weld to base metal transition, absence of defects (pores, oxide inclusions and hot solidification cracks), due to metal melting and solidification in the welding zone at GTA welding, and formation of a fine-dispersed deformed structure of welds.

3. Owing to high indices of cyclic crack resistance of D16T alloy welded joints, produced by friction stir welding in the solid phase, their high structural strength is ensured that expands the possibilities for this alloy application in aerospace engineering.

To determine the range of operating voltages of the plasmatron MP-04 of installation MPN-004 for microplasma spraying, a family of volt-ampere characteristics was plotted, each of which was measured at the constant composition and consumption of the working gas, length of the arc open section and the design dimensions of the plasmatron. The heat flux was determined by the continuous-flow calorimetry method. It allowed under the conditions of microplasma wire spraying to determine the thermal efficiency of the plasmatron, the average-mass initial enthalpy and the plasma jet temperature depending on the plasmatron operation mode: arc current and plasma-forming gas consumption. 12 Ref., 7 Figures.

Keywords: microplasma wire spraying, wire materials, argon plasma jet, volt-ampere characteristics of plasmatron, temperature and enthalpy of plasma jet, thermal efficiency coefficient, voltage and current of plasma arc, consumption of plasma-forming gas

As to the type of spraying materials, the technology of thermal spraying (TS) of coatings is divided into powder and wire spraying [1]. The technology of powder TS is distinguished by the variety of types and compositions of spraying materials and possibility of using powders with different granulometric composition. However, it has a number of drawbacks associated with the difficulty in providing the accurate and stable supply of powders into the spraying gas jet, as well as the need in using special powder batchers: complex and expensive devices.

The difference in the size of particles, inherent to all the powders for TS, creates a problem of their non-uniform heating, which influences the quality of coatings. In case of wire TS, by controlling the supply of spraying material (wire), its accurate and stable introduction into the atomizing gas jet and the guaranteed formation of flow of wire spraying molten products are provided. The disadvantage of this process is that the composition of the spraying material is limited by ductile metals. However, recently, the expansion of application of flux-cored wires alleviates this drawback to a certain degree.

In practice, the wire TS is represented by the processes of electric arc metallization, gas flame wire spraying and, in a slightly smaller volume, by plasma TS with the use of «neutral wire» and «wire–anode» spraying systems [2].

The technology of microplasma spraying of coatings (MPS), developed at the E.O. Paton Electric Welding Institute, used the technology of powder spraying at the first stage. For its realization, a design of a plasmatron was made, characterized by a remote anode and presence of a channel for shielding gas supply, protecting plasma jet [3].

The formation of plasma jet, distribution of temperature values and velocities in its volume, is determined both by the plasmatron operation parameters, as well as by its design. In this connection, when creating a new design of a plasmatron, the necessary stage in the development of a spraying technology with its use is the determination of its main characteristics and the limiting levels of temperatures and velocities of plasma jet. This evaluation is necessary to determine the capabilities of the plasmatron for heating and melting the particles of the spraying material.

When developing the technology of microplasma spraying of coatings using a neutral wire, it was necessary to study the characteristics of the microplasmatron and the microplasma jet, generated by it in the conditions of spraying with wire materials.

The aim of the experiment is to investigate the thermal efficiency of the plasmatron operation $\eta$ and to determine the average-mass initial enthalpy and temperature of the plasma jet depending on the plasmatron operation modes: arc current $I_a$ and plasma-forming gas consumption $Q_{pg}$.

Procedure for determining characteristics of microplasmatron for conditions of MPS. Plasmatron is the converter of electrical energy into heat one.
Therefore, on the one hand, the arc of the plasma jet as an element of electrical circuit is characterized by electrical parameters (current, voltage), and on the other hand, as a source of heat, it is characterized by thermal parameters (temperature, heat content). There is a complex relationship between the parameters of the first and the second group.

Enthalpy ($\Delta H$) is the amount of heat contained in a unit of volume or mass of the jet, is an important thermal parameter of the plasma jet. The effect of consumption and composition of working gas on the arc voltage is graphically illustrated by the volt-ampere characteristics of plasmatrons (VAC), representing the dependence between the voltage and arc current at the other equal conditions (arc length, plasmatron parameters, external conditions). In the region of low currents, the VACs of plasmatrons are falling, and with the current growth they pass into independent and rising ones. With an unchanged gas composition, the intensity of all sections of the plasma arc column increases with increasing the degree of its compression. The degree of the arc column constriction is growing (to a certain extent) with a decrease in the forming nozzle diameter and an increase in the consumption of working gas. As investigations show, the gas main mass passes through the peripheral regions of the column and, as the consumption increases, it chills and constricts the column ever more intensively. The more intensively the arc is constricted, the lower the value of the current, at which VAC transfers into rising one. Thus, the plasma arc voltage depends on the design dimensions of the plasmatron, on the arc current, composition and consumption of the working gas [4–6].

To determine the range of operating voltages of the plasmatron, the VAC family is plotted, each of which is taken at change in the consumption of the plasma-forming gas $Q_{pg}$ and unchanged design dimensions of the plasmatron.

For experiments, the plasmatron MP-04, designed by the E.O. Paton Electric Welding Institute, was used. The measurements were carried out with a channel diameter of the plasma-forming nozzle of 1.0 mm and an electrode diameter of 1.5 mm. The distance from the electrode end to the nozzle edge was 1.0 mm, the distance from the nozzle edge to anode was 1.5 mm. As a plasma-forming and shielding gas, argon was used. The plasma-forming gas consumption changed within the limits of 100–300 l/h. The shielding gas consumption in all the experiments was maintained at 400 l/h.

The losses for heating of the plasmatron parts were evaluated according to the methods described in works [7, 8], according to the value of the heat flux $Q_f$.

The losses for heating of the plasmatron parts were evaluated according to the methods described in works [7, 8], according to the value of the heat flux $Q_f$.

Assuming that the plasma is optically thin (transparent for its own radiation), the losses on radiation (taking into account that during operation of the plasmatron MP-04 the arc is burning outside the plasmatron body, i.e. between the remote anode and the cathode tip) can be estimated from the formula:

$$P_{rad} = \frac{\pi d^2}{4} H \psi (T),$$

where $d$ is the arc column diameter; $l$ is the open arc section length; $(\pi d^2/4)l$ is the plasma volume; $\psi$ is the

$\frac{c \rho Q_w \Delta T}{P_a}$

where $c$ is the heat capacity of water, J/(g·K); $\rho$ is the density of water, g/cm$^3$; $Q_w$ — water consumption, cm$^3$/s; $\Delta T$ is the difference of water temperature at the inlet and outlet from the calorimeter, °C.

The water consumption through the calorimeter (sections of the calorimeter) was measured by rotameters RS-5, the difference in temperatures $\Delta T$ was measured by mercury thermometers with a division value of 0.1 °C. The heat flux was determined by the method of continuous-flow calorimetry in the experimental installation, the scheme of which is shown in Figure 1.

The thermal efficiency of the plasmatron was calculated from the ratio:

$$\eta = 1 - \frac{P_h}{P_a},$$

where $P_a$ is the arc power, determined as the product of $I_a U_a$, W; $P_h$ is the heat flux power consumed for heating the water-cooled surfaces of the plasmatron (copper anode, cathode unit and plasma-forming nozzle), which is determined by the value $Q_w$ and the heat losses for radiation $P_{rad}$:

$$P_{H} = Q_w + P_{rad}.$$
The enthalpy $\Delta H (J/l)$ of the plasma jet was determined from the ratio:

$$\Delta H = \frac{P_a \eta}{Q_{pg}}$$  \hspace{1cm} (4)

where $Q_{pg}$ is the consumption of the plasma-forming gas, l/h; $\eta$ is the thermal efficiency of the plasmatron; $P_a$ is the arc power, J/h.

The jet temperature was determined from the Tables of its relationship with the enthalpy in work [9].

**Measurement of VAC of microplasmatron MP-04 during wire spraying.** VAC of the plasmatron demonstrates the relation between the voltage of plasma arc and current. VAC allows establishing the range of stable operation of the power source during change in the operation modes of the plasmatron.

The voltage of the plasma arc depends on the design dimensions of the plasmatron (nozzle diameter, nozzle length), arc current, composition and consumption of the working gas and on the value of interelectrode gap.

The main thermal characteristics of the plasmatron are the thermal efficiency of its operation $\eta_{htg}$, enthalpy $\Delta H$ and the temperature of plasma jet.

A calculated evaluation of the influence of parameters of the plasmatron operation mode on the enthalpy of plasma jet was carried out using the expression (4). With the increase in the arc power $P_a$, the temperature and the enthalpy $\Delta H$ of plasma jet increase. The effect of the consumption of plasma-forming gas $Q_{pg}$ is opposite. The arc power is in its turn determined by two parameters: current and voltage.

To determine the range of operating voltages of the plasmatron MP-04, a family of VAC was plotted, each of which was taken at the unchanged composition and consumption of the working gas, length of the arc open section and constant design dimensions of the plasmatron (Figure 2).

The processing of the experiment results shows that VACs of the plasmatron MP-04 are rising and have a linear form. It is known that in most cases the rising VACs are more energetically advantageous, because during the use of power sources they do not require introduction of additional ballast resistance to the circuit, the voltage drop at which can reach 50% [10]. Thus, the rising VACs of the microplasmatron MP-04 allow using the power sources with both steep-falling external VAC, as well as with rigid external VAC for operation with it [11].

It was established that at a constant «cathode–anode» distance and constant composition of the gas, the voltage increases linearly with increase in current and consumption of plasma-forming gas (Figures 2 and 3), at the same time, the power of plasmatron increases.

The growth in voltage at the increase in working gas consumption can be explained by the increase in the degree of the arc column constriction. During blowing of arc discharge at its boundary due to intense heat exchange between the gas and the arc column, the deionization process takes place, which leads to reduction in the discharge diameter and growth in the electric field intensity in it. The more intensively the arc is constricted, the lower value of current is required for the VAC to go into rising one.

It is seen from the VAC (Figures 2 and 3) that for operating values of current and consumption of plasma-forming gas, the voltage is in the range of 25–50 V. Using the dependence given in work [12], one can assume that the power source for the arc exciting and stable operation of the plasmatron MP-04 at the modes providing spraying of wire materials, should be capable for smooth regulation of current in the range of 20–80 A and the open-circuit voltage of not less than 60 V.

The investigations of thermal efficiency of microplasmatron showed that a change in current from 15 to
60 A in the entire consumption range of plasma-forming gas of 100–300 l/h almost does not result in its change (Figure 4). It was established, that thermal efficiency of the plasmatron grows with the increase in the consumption of plasma-forming gas in the range of 100–200 l/h, and in the range of consumption of 200–300 l/h, the efficiency growth is not observed. This is explained by the balance beginning between the energy, which is taken by the plasma-forming gas and cooling system of the plasmatron, as well as by the beginning of critical conditions, at which the arc constriction is maximum and the losses to the nozzle walls remain at the same level. The maximum efficiency of the microplasmatron MP-04 reaches 75 %, which exceeds the result obtained in the conditions of powder MPS [12].

The carried out investigations showed that the efficiency of the plasmatron MP-04 is almost not changed with a change in the current at the gas consumption, exceeding 100 l/h (Figure 5).

**Determination of enthalpy and temperature of argon plasma jet in microplasma wire spraying.**

During microplasma wire spraying, for improvement of the wire melting conditions and dispersion of the molten metal drop, formed at the end of the neutral wire and formation of a jet, containing the particles of the spraying material, an increased gas consumption at a low plasma arc current is used. Therefore, the enthalpy of the plasma jet is much lower than that in microplasma powder spraying. In Figure 6 it is seen that with the increase in gas consumption at a less intensive increase in the jet power, the values of the enthalpy and temperature of the plasma jet are reduced.

The carried out calculation of plasma parameters allowed determining the temperature of microplasma jet from the data of argon temperature dependence on the enthalpy [9]. The maximum temperature of the jet is 17700 K at the minimum gas consumption (100 l/h) and the maximum current (60 A), and the minimum temperature is 5000 K at the maximum gas consumption (300 l/h) and the minimum current (15 A) (Figure 6).

At a fixed voltage, the arc power can be controlled by the more flexible parameter: arc current. The jet enthalpy increases linearly at all the gas consumptions with increase in current and hence, in arc power (Figure 7).

Since the voltage is mainly determined by the design of the plasmatron and the composition of plasma-forming gas, the selection of its operating mode during spraying process consists in establishing the

**Figure 4.** Variation in thermal efficiency of the plasmatron MP-04, depending on the consumption of plasma-forming gas at different values of current A: 1 — 15; 2 — 30; 3 — 45; 4 — 60

**Figure 5.** Variation in thermal efficiency of the plasmatron MP-04 as a function of current at different values of consumption of plasma-forming gas, l/h: 1 — 100; 2 — 150; 3 — 200; 4 — 250; 5 — 300

**Figure 6.** Variation in enthalpy depending on gas consumption for different values of current A: 1 — 15; 2 — 30; 3 — 45; 4 — 60

**Figure 7.** Variation in enthalpy depending on current for different values of consumption of plasma-forming gas, l/h: 1 — 100; 2 — 150; 3 — 200; 4 — 250; 5 — 300
optimal combination of current and consumption of the plasma-forming gas. The lower and the upper level of consumption of the plasma-forming gas is connected with the operating conditions of the microplasmatron (thermal load at the nozzle walls, anode life, process stability).

Conclusions

As a result of measuring the electrical and thermal characteristics of a turbulent microplasma argon jet during spraying the neutral wire, it was established that under these conditions the VAC of a microplasmatron with a remote anode increases linearly in the range of currents of 10–60 A for the consumption of plasma-forming gas of 100–300 l/h, and the efficiency of the microplasmatron is almost independent of the current value and increases from 48 to 73 % with an increase in the plasma-forming gas consumption from 100 to 200 l/h. A further increase in the consumption of the plasma-forming gas to 300 l/h does not lead to a change in the efficiency. The calculated value of the plasma jet enthalpy under these conditions reaches 40 kJ/l, which is equivalent to the argon jet temperature of 17700 K.

The paper presents the results of experimental studies and engineering developments, which were the base for creating a technology and technique of performance of electroslag welding with consumable nozzle of reinforcing elements of building columns of a high-rise building. Experience of application of the developed technology in construction of a high-rise building is described. New machines and special technological fixture at performance of welding operations under assembly conditions was demonstrated. 15 Ref., 7 Figures.

Keywords: building columns, girths, reinforcing elements, electroslag welding, consumable nozzle, special technological fixture, assembly conditions, efficiency of welding operations

One of the specific features of application of welding processes in construction is strict compliance of the terms of welding operations performance with the terms of construction and mounting work. Special requirements are made of welding technologies to ensure simultaneous performance of this work, namely high process efficiency, mobility, higher reliability of welding equipment and its insensitivity to unfavourable (field) conditions of operation, low labour consumption, minimum time consumed by assembly-preparatory operations.

In recent years, a significant growth in the construction of high-rise administrative buildings necessitated application of rolled metal of increased thickness (60 mm and greater) by design institutes for manufacturing all-welded bearing columns. At present the girths of building columns and reinforcing elements of their opening frames are joined by coated-electrode manual or mechanized welding with solid or flux-cored wire, i.e. the methods, which are characterized by high labour consumption and low efficiency for the above thicknesses that significantly prolongs the terms of construction and mounting work.

At the initial stage of construction of basement flooring at erection of high-rise «Community Center» experimental building (Kiev) it became necessary to significantly increase the welding operations efficiency. It was proposed to replace coated-electrode arc welding by electroslag welding, as the most productive method of joining metals of unlimited thickness [1] that was the objective of this work.

Electroslag welding (ESW) was applied for the first time in the USSR at construction of blast furnace jackets, mounting of metal structures of industrial buildings, large-capacity converters, processing apparatuses for alumina plants, massive water conduits, etc. [1]. Also known is the experience of successful application of ESW in the USA and Japan in fabrication of massive building structures for administrative buildings [2–6]. ESW was applied for making longitudinal butt joints of T- and I-beams in fabrication of heavy building columns [3], as well as joining corner columns with support plates and diagonal braces [5]. Here, the method of consumable-nozzle ESW (CNESW) became the most widely accepted for fabrication of all-welded columns for steel frames of 52–59-storey buildings due to the possibility to weld elements of different thickness from 44 to 73 mm [7]. At present CNESW is widely applied in these countries for joining inner diaphragms 40–150 mm thick to girths of building columns of a rectangular profile [8, 9] at their fabrication under production conditions.

According to Production Project the design of the building columns of 54-storey «Community Center» experimental building under construction resembles the shape of the Maltese cross in its cross-section (Figure 1). It was necessary to weld reinforcing elements 2 (90 mm thickness, 800–1450 mm length) to the opening frames located between the end faces of girths 1 with the purpose of subsequent erection of basement flooring on their base. Column girths were made from new structural steel 06GB-390 (TU U 27.1-05416923-085–2006) 50 mm thick, and reinforcing elements of their opening frames were from steel 09G2S-15 (GOST 19281–89). A feature of steel 06GB is its good weldability, high delayed and cold cracking resistance, compared to the known grades of low-carbon steels of this strength class [10].

ISSN 0957-798X THE PATON WELDING JOURNAL, No. 9, 2018

23
According to project documentation, a V-shaped groove was specified in the points of welding the reinforcing elements to building column girths, which is designed for performance of multipass electric arc welding in the vertical position (of the order of 300 passes). For application of single-pass CNESW it was necessary to develop a special technology and technique of joining the reinforcing elements to the column.

In connection with the non-standard groove shape, adverse working conditions in the underground space (high humidity, abrasive and cement dust), as well as complexity of formation of the reverse side of the butt joint, the following problems had to be solved to reach the defined goal:

- develop the technology and technique of ESW performance, ensuring guaranteed fusion of filler metal with base metal, sound formation of weld metal and absence of defects;
- develop and manufacture portable welding machines of higher reliability, where the control systems are protected from possible penetration of moisture and dust, that is characteristic for operation in site conditions. Machine design should provide their fast mounting on the item, as well as dismantling;
- develop special devices for quick mounting of welding machines on building columns;
- develop technological fixture, ensuring sound formation of outer and reverse sides of the electroslag weld, as well as devices for its fast mounting and dismantling, particularly in difficult-of-access sections.

To solve the defined tasks we have conducted design work and experimental studies. CNESW parameters were optimized on full-scale samples, made from the above-mentioned steels, using a DC power source. Sv-08G2S electrode wire and AN-8U welding flux were used as welding consumables. Welding speed was 1.6–2 m/h to reduce the heat input.

Transverse templates were cut out of the welded samples to determine the mechanical properties and chemical composition of welded joints. Microhardness measurements were performed by contact-resonance hardness meter TKR-35. Transverse macrosection of welded joints, scheme and results of hardness measurements are shown in Figure 2, from which one can see that hardness distribution in the studied sections is characteristic for ES welds of analogous steels, not subjected to subsequent heat treatment. Here, considering the sequential performance of adjacent welds, as well as close location of welded-up grooves, one can see from Figure 2, that the heat, evolved when making the second weld, produced partial auto-heat treatment of metal of the previous weld and part of the heat-affected zone (HAZ).

Visual inspection of welded samples after CNESW of V-shaped butt joints is indicative of satisfactory formation of weld surface. Welds are tight, without slag inclusions, pores, lacks-of-fusion or cracks. Figure 3 shows the results of determination of chemical composition of metal of a column girth, reinforcing element, welding wire and weld, from which it follows that the weld metal composition differs only slightly from that of the steels being welded, and low content of carbon and increased content of manganese in the weld metal ensure a high level of technological strength of the welded joint.
Values of mechanical strength of welded joint metal were determined from the side of column girth. Tensile tests of samples showed that ultimate strength value \( \sigma_t \) for metal along the fusion line and in the HAZ at 5 mm distance from the fusion line is equal to \( \sigma_t = 466–480 \) MPa, that is indicative of a sufficient level of welded joint strength at ESW of steels 06GB and 09G2S. Values of impact toughness after testing at the temperature of 20 \( ^\circ \)C in the as-welded condition for metal along the fusion line and in the HAZ at 5 mm distance from the fusion line are equal to \( KCU = 108–155 \) J/cm\(^2\).

Analysis of the given results of CNESW of butt joints, earlier to be joined by electric arc welding, as well as positive experience of operation at above zero ambient temperatures of welded structures, not sub-

**Figure 3.** Chemical composition of the metal of girths reinforcing elements, electrode wire and weld: 1 — 06GB; 2 — 09G2S steel; 3 — Sv-08G2S; 4 — weld

**Figure 4.** Fastening A-1304 machines on a building column: 1 — column; 2 — welding machines; 3 — quick-detachable frame

**Figure 5.** Sequence of assembly and consumable-nozzle electroslag welding of reinforcements of building column opening frames: 1 — column girth; 2 — water-cooled coverplate; 3 — reinforcing element; 4 — consumable nozzle; 5 — technological tab; 6 — weld; 7 — forming coverplate on the reverse side of butt joint; I—VIII is the weld stacking sequence
jected to postweld heat treatment [11], are indicative of technical possibility and rationality of its application for welding the reinforcing elements of opening frames of columns of Maltese cross type.

Considering the short construction time, at the first stage it was proposed to adapt for CNESW batch-produced A-1304UKhLCh welding machines for their application under specific conditions of construction work performance in underground premises. A special quick-detachable frame (Figure 4) was developed and manufactured for fastening the machines on the columns. It allows quickly mounting and dismantling the systems after welding the butt joints.

Reliable containment of the slag and metal pools in the gap is provided by copper water-cooled devices from the outer and reverse sides of the welded butt joint [1]. Nonstandard shape and dimensions of the groove, as well as difficult access for servicing the reverse side of the butt joint (Figure 1), required application of forming devices of a special design. Customized technological fixture was developed and manufactured to ensure sound fusion of filler metal with base metal and satisfactory weld formation, namely water-cooled forming devices and fixtures for their quick fastening on the item being welded [12, 13].

In order to lower the level of residual welding stresses, welding of eight butt joints on each column was performed with simultaneous application of two welding machines and with specific stacking order of welds at higher welding speeds (Figure 5).

Considering the prohibition for oxy-fuel cutting application at construction of the above building, as well as to reduce the welding time and save welding consumables, a technological measure was implemented, resulting in maximum reduction of the size of the crop parts of welds by welding-up the shrinkage cavity on the welded butt joint linear part (Figure 6).

After transfer of the developed technology to Ukritarm Company (Kiev) and training its personnel in the technique of CNESW performance, the latter performed welding of reinforcing elements of opening frames on eight columns (64 butt joints) in construction of the flooring of the first basement storey. However, during performance of the above work, some problems were encountered in operation of A-1304 machines. A large weight of the machines greatly increased the labor consumption and time for assembly-preparatory operations. The electric components of the machines failed periodically, because of the high humidity and dustiness of the locations of welding operations performance. To solve the above problems, PWI developed portable AShP 113M2 machines for CNESW with two electrode wires in site,
which is devoid of the above drawbacks [14]. Two pilot-production ASHP 113M2 machines were manufactured and transferred to the customer for welding operations performance in the object under construction. New machines were used to successfully weld more than 1500 butt joints (more than 1250 run. m of welds) in construction of eight basement storeys (Figure 7) [15]. Ultrasonic testing of welded joints did not reveal any defects in the form of cracks, pores, lacks-of-fusion, etc.

**Conclusions**

1. Technology and technique for performance of CNESW of reinforcing elements of building columns opening frames were developed, which provide guaranteed fusion of filler metal with base metal, sound formation of weld metal and absence of any defects. Labour consumption of assembly-preparatory and welding operations was essentially reduced, process efficiency was increased by more than 20 times, compared to coated-electrode manual welding, and production standards were improved.

2. Application of new portable ASHP 113M2 machines ensured their trouble-free operation under the conditions of high humidity and presence of cement dust during the entire cycle of welding operations.

3. Application of developed special technological fixture ensured reliable containment of slag and metal pools in the welding gap, also in difficult-of-access sections, and allowed an essential reduction of labour consumption of assembly-preparatory operations.

4. New technology and equipment can be recommended for welding in site of massive building columns, thick-walled tanks and other metal structures, operating at positive ambient temperatures.

EFFECT OF ALLOYING CHARGE AND EXTERNAL MAGNETIC FIELD ON STRUCTURE AND PROPERTIES OF DEPOSITED METAL

V.V. PEREMITKO, V.L. SUKHOMLIN, O.L. KOSINSKAYA and A.I. PANFILOV
Dniprovsk State Technical University
2 Dneprostroevskaya Str., 51918, Kamenskoe, Ukraine. E-mail: welding@dstu.dp.ua

Effect of inducing the external magnetic field in arc surfacing over preliminary deposited alloying charge (carbon-containing fibers + SiO$_2$) on hardness and structure of metal, as well as on change in the above-mentioned indices within the limits of single beads was investigated. It was found that the carbon-containing fibers applied to the part surface being deposited cause during surfacing the local enrichment with carbon of a liquid phase, which is decayed in cooling for ferrite-carbide mixture, that leads to the increase in metal hardness. Additional inducing the external magnetic field in process of surfacing promotes intensive stirring of weld pool that results in producing the more uniform structure and hardness. The analytical dependencies of hardness of deposited layers on amount of carbon-containing fibers, SiO$_2$ + Fe and magnetic field induction were obtained. The results of investigations can be used in development of technology for manufacture and restoration of parts operated under the abrasive wear conditions. 9 Ref., 1 Table, 10 Figures.

Keywords: submerged-arc surfacing, carbon-containing materials, modifying components, external magnetic field, deposited metal, hardness, microstructure

Submerged electric arc surfacing over the alloying charge is one of the simplest and most economical methods to produce wear-resistant layers on the surface of parts, operated under the conditions of different types of abrasive wear [1–3]. It is also known that using this method of surfacing, the producing of deposited metal of a preset and homogeneous chemical and microstructural composition depends to the greatest extent on the mode of surfacing, chemical and fractional composition of alloying charge, over which the surfacing is performed [4, 5].

The aim of this work was the improvement of this method of surfacing by the use of carbon-containing and modifying materials as the alloying charge. As the basis the scheme of arc surfacing of high-carbon coatings over the layer of charge was taken, where it was used in the form of carbon fibers [6]. Additionally, in order to improve the chemical and structural homogeneity of the deposited metal, the effect of an external magnetic field on this parameter was investigated, which according to some data [7, 8] has a positive effect on these properties.

In the course of experiments, the carbon fibers were preliminarily put on the surface deposited in strips (Figure 1). During surfacing, the electrode wire was placed so that the depositing bead 2 overlapped the carbon-containing strip approximately by 25–35 %.

As a material, which fixes the placement of carbon fibers (2–4 fibers T 700SC Torey per the bead) on the surface deposited, a primer-based mixture was used, to which iron powder (15–25 wt.%) and aerosil (0.6–1.2 wt.%) were added. The layout of carbon-contain-

Figure 1. Scheme for the introduction of additional materials: 1 — specimen; 2 — deposited bead; 3 — carbon-containing material; N — displacement; e — bead width
ing fibers on the surface deposited is shown in Fig.

ure 2.

In the experiments on surfacing, the automatic welding machine ADS-1000 with the rectifier VDU-

06 was used. The surfacing was performed with the wire Sv-08A of 3 mm diameter under the flux AN-

4A at a direct current of reverse polarity. The surfacing mode: current is 400–420 A, arc voltage is

32–36 V , wire feed speed is 160 m/h, surfacing speed is 12–16 m/h, pitch is 6–8 mm. The material of the specimens is steel 09G2S (hardness as-delivered is HB

128–143). In order to induce the external magnetic field, a special coil was used, which was fixed on

the torch nozzle of the automatic machine ADS-1000. The coil was supplied by direct current.

During the experiments, the second order central noncompositional planning for three factors was per -

formed: the concentration of SiO$_2$ + Fe, the amount of introduced carbon-containing fibers and induction of external magnetic effect. From the deposited beads

the specimens were cut out to investigate the microstructure and hardness.

Based on the obtained data, the highest values of hardness of the deposited metal are fixed at the periph-

ery of the deposited beads, an expressive maximum is observed at the magnetic induction $B = 60$ mT; SiO$_2$ + Fe — 0.8–1.0 wt. %; n — 4 pcs (see Table and Fig-

ure 3).

The processing of the experimental data was car-

ried out using the program STATISTICA 6.0 (Fig-

ures 4 and 5). Having compared the diagrams shown in Figures 4 and 5, it can be concluded that at the point 2 (the place, where additional materials were applied) at the same modes of surfacing, the increase in the hardness $HRC$ by 8–10 units is observed.

$^*$Places of hardness measurements (see Figure 3).

*Figure 2. Scheme for the introduction of additional materials: 1 — deposited bead; 2 — carbon-containing fibers fixed by the primer before surfacing.

With the increase in the number of carbon-containing fibers and magnetic induction, the hardness of the weld metal also increases. However, as the practice shows, at the magnetic induction values higher than 70 mT, the pores appear due to intensive stirring of the molten metal pool. The equation, describing the influence of all factors, has a form:

$$HRC = 14.17 + 0.14[c] + 2.72[SiO_2] + 2.57B -$$

$$-2.03[SiO_2]^2 + 0.1B^2 + 0.0027[c][SiO_2] -$$

$$-0.035[c]B + 0.49[SiO_2]B,$$

where [c] is the number of carbon-containing fibers in the deposited layer, pcs; [SiO$_2$] is the concentration of aerosil, wt. %; B is the induction of magnetic field, mT.

Figure 6 shows the diagrams of changes in the hardness of metal on the deposited bead according to the traditional scheme of surfacing and that used in the investigations.

Thus, when adding additional materials in the form of aerosil and carbon-containing fibers T700Sc Torey, 1.5–2.0 times increase in the hardness is ob-

served, the highest hardness is fixed at the periphery of the beads.

After measuring the hardness, the analysis of microstructures was carried out. Figures 7–9 show the microstructures of specimens 1, 3, and 6 in the zones 1, 2, and 3 (see Figure 3 and Table). Comparing the structure of specimens 1 and 3 in the zone 1, it is possible to note a noticeable refining of both ferritic component, as well as the areas with the ferrite-cementite mixture.

*Figure 3. Scheme for measuring hardness of the deposited bead.*
In the specimen 1, the size of quasi-polygonal grains of ferrite is 20–40 μm, and in the specimen 3 it is 10–30 μm. The grains of ferrite-cementite mixture have a size of 40–60 μm in the specimen 1 and 30–40 μm in the specimen 3 (Figure 7, a, b).

Such refining of structural elements in the specimen 3 is explained by the influence of an external magnetic field during arc surfacing [8]. The additional stirring of the molten metal in a pool facilitates the growth of cooling rate, and, therefore, increases the degree of overcooling during solidification and refining of all the structural components.

In the zone 2, the formation of a structure is influenced not only by carbon-containing fibers and aerosil, but also by an intense heat removal to the base metal. Under its influence, the primary ferrite partially changes its morphology: the acicular ferrite appears in the structure [9]. Also under the effect of a directional heat removal the ferrite-cementite mixture acquires a noticeably elongated shape. The pearlitic structures are formed in the form of thin interlayers between the laths of acicular ferrite or in the form of coarse grains of a quasi-eutectoid. The ferritic formations in zone 2 of the specimen 1 have a width of 30–40 μm and are elongated by 150–200 μm, in the specimen 3 they are elongated, respectively by 15–20 μm and 80–150 μm.
The factor of the magnetic field (for the specimen 3) facilitates stirring of weld pool metal and a more uniform distribution of SiO₂ particles, which play the role of a modifier of the second type, increasing the amount of solidification centers, and the carbon-containing fibers in the zone 2 supply carbon for the formation of a carbide phase. These two factors not only facilitate the refining of the final structure, but also increase the fraction of ferrite-cementite mixture in the specimen 3 (Figure 8, a, b). The hardness in this zone is maximum.

In the zone 3 of the specimen 1, the lowest hardness is noted. Without additional magnetic effect, the formation of gradient structures occurred almost without the participation of aerosil SiO₂ particles. The width of the ferritic areas in this zone is 25–35 μm, the length is 180–250 μm. The areas of the ferritic-pearlitic mixture have a width of 50–80 μm and a length of 250–300 μm. The width of the acicular ferrite lath is 20–40 μm at an average length of up to 90 μm.

The structure of specimen 3 in the zone 3 was formed with the participation of SiO₂ particles and an external magnetic field. In this zone, the width of the ferritic areas in the structure of columnar crystallites reaches 20–35 μm with a length of 140–180 μm, the width of the areas of ferritic-pearlitic structure is 35–50 μm with a length of 200–230 μm. The width of the acicular ferrite lath is 15–20 μm at an average length of up to 45–70 μm (Figure 9, a, b).

In the specimen 6, unlike the specimen 3, twice lower content of SiO₂ and twice higher content of carbon-containing fibers were used. First of all, these changes affected the zone 1. The structure in this zone, due to a smaller amount of modifier, intensive stirring by a magnetic field and additional amount of carbon, has a uniform distribution of quasi-polygonal ferrite areas of 20–30 μm in size, grains of ferrite-cementite mixture with sizes of 35–55 μm and acicular ferrite at a width of the lath being 10–20 μm and a length of 30–55 μm.
A large total volume of ferritic-carbide mixture (up to 50 %) in combination with acicular ferrite (up to 20 %) contributed to an increase in the hardness $HRC$ of the specimen in the zone 1 by 3.9 units as compared to the specimen 3. In the zones 2 and 3, the increase in hardness is also predetermined by the refining of both the ferritic component of the structure, and the areas of the quasi-eutectoid and the acicular ferrite laths, which led to higher $HRC$ values among all the specimens (Figure 10, $a$–$c$).

Conclusions

1. The analytical dependences were proposed to determine the hardness of deposited layers on the number of carbon-containing fibers, previously applied on the surface deposited, the concentration of $\text{SiO}_2 + \text{Fe}$, and the external magnetic field induction.

2. It was established that carbon-containing fibers applied on the part surface deposited cause a local carbon enrichment of the liquid phase during surfacing, which decomposes into a ferritic-carbide mixture during cooling, thus leading to an increase in the hardness of the metal. The additional inducing of external magnetic field in the process of surfacing promotes an intensive stirring of the weld pool, which results in a more uniform structure and hardness of the deposited metal.

3. The use of aerosil $\text{SiO}_2$ as a modifier is the most justified in the combination with the inducing of an external magnetic field during surfacing. The hardness of metal after using this technology is increased in the near-surface area of the deposited metal by about 20 %.

4. The obtained results can be used in the development of technology of surfacing the parts operated under the conditions of intensive abrasive wear.

CONTROL OF THE PROCESS OF BASE METAL PENETRATION AT END FACE ELECTROSLAG SURFACING IN CURRENT-SUPPLYING MOULD*

V.G. SOLOVIOV and Yu.M. KUSKOV
E.O. Paton Electric Welding Institute of the NAS of Ukraine
11 Kazimir Malevich Str., 03150, Kyiv, Ukraine. E-mail: office@paton.kiev.ua

In the absence of discrete filler of a certain chemical composition, there appears the task of performing end face electroslag surfacing with large-section electrodes. Here, one of the main surfacing quality characteristics is achieving the minimum and uniform penetration of the base metal. Main principles of design of the system of automatic regulation of these parameters at end face electroslag surfacing in a current-supplying mould were developed. Schemes of control of current distribution in the current-supplying mould are proposed, which allow regulation of the process of electrode melting, and, thus, indirect control of the quality of base metal penetration. A particular scheme should be used to produce a sound bimetal joint with provision of regulation of the position of remelted electrode end face in the slag pool relative to the current-supplying section of the mould and maintaining the calculated heat level of the slag pool. 9 Ref., 7 Figures.

Keywords: automation, regulation, penetration, end face electroslag surfacing, current-supplying mould, electrode, conductivity

A method of electroslag surfacing (ESS) in a current-supplying mould (CSM) developed at the E.O. Paton Electric Welding Institute to the largest extent shows its advantages at melting of different type discrete filler materials in a slag pool [1]. Nevertheless, in a series of cases, for example at absence of filler with specific composition, difficulty and high price of its manufacture as well as with the availability of the billets, which can be used for relatively simple manufacture of the remelted electrodes, there is a task to carry out ESS, in particular end face, with large-section electrodes. Moreover, the practice showed that such a method of surfacing under certain conditions allows achieving increased process efficiency with providing its high quality.

Technologies of ESR with canonic electrode-bottom plate monofilar diagram of connection to power source are well studied and in the majority automated [2, 3] in contrast to ESS using end face electroslag surfacing in CSM with upper current-supplying section. One of the main index of surfacing quality is production of minimum and uniform penetration of base metal. This paper is dedicated to development of the basic principles of design of a system for automatic regulation of these indices in end face ESS with large section electrode.

The synergy principles of synthesis [4], stabilizing relationship between the variables of process states are used more often in the recent time for automation of the dissipative systems, to which ESS is referred. Thus, it is possible to achieve degeneration of the dynamic equations of ESS process and presence of integral invariants of manifolds in the space of its states. The invariant manifolds present themselves «some functions, which do not change during movement». Such approaches to automation of the nonlinear objects significantly simplify synthesis of the system. The processes taking place in the mould during electroslag surfacing are determined by number of factors, which in most cases cannot be controlled by operator all the time using the equipment and being evaluated by his/her intuition. Moreover, the level of reliability of such evaluation depends on operator experience. Therefore, for solution of the problem of automation of surfacing process in CSM it is necessary to find the possibility of indirect estimation of the values of parameters, necessary for automation, analyzing electrotechnical processes in the mould and current-supplying circuits.

Large effect on repeatability of the surfacing results can have not only modes and technique of electroslag process itself, but also variation of electrical parameters of the electric circuits out of mould working zone. In particular, length and location of cables influence characteristics of surfacing process. For example, in the case with ESS in CSM of 200 mm diameter at up
to 3 kA currents and cable lengths around 10 m the voltage drop at them can reach 15–25 V. Besides, it is necessary to take into account presence of «valve-like effect» in a slag pool [5], which introduces nonlinearity and deteriorates shape of sine wave in connection of alternating current power sources [6, 7]. The same effect shall be considered when selecting polarity of connection of direct current sources to the mould.

Layout of electrical diagram of CSM connection. Figure 1 presents the diagram of ESS in CSM with one power source and its electrical equivalent diagram.

There is a possibility of automatic control of electric parameters of current-supplying elements, which determine a mould working zone (MWZ), i.e. current-supplying section of the mould, slag pool, electrode and bottom plate. It is necessary to measure voltage between the electrode and current-supplying section of the mould \(U_\text{e-m}\), electrode–bottom plate \(U_\text{e-b}\), current-supplying section of the mould and bottom plate \(U_\text{m-b}\), mould current \(I_\text{m}\), electrode current \(I_\text{e}\) and bottom plate current \(I_\text{b}\). However, indicated parameters themselves are not representative in order to characterize the process. There is a need in more generalized, complex parameters having higher correlational relationship with processes taking place in the mould working zone, which are «integral invariants of manifolds» of occurring thermodynamic and electrochemical processes in MWZ.

Independent on connection diagram of the source (sources) to current-supplying elements of the working zone in accordance with Kirchhoff’s first law one of the currents (sum current, marked as \(I_\text{sum}\)) will be always determined by sum of two other currents (component currents, marked as \(I_\text{com}\)).

For example, if \(I_\text{e}\) is \(I_\text{sum}\), than \(I_\text{m}\) and \(I_\text{b}\) are \(I_\text{com}\). Based on such presentation of electrical connections of inputs and outputs of the working zone it is possible to talk about the parameters, which to some extent characterize the internal processes in the mould, namely this is electrical conductivity of inner channels of the mould working zone along the channels that refer to \(I_\text{com}\). In our example these are conductivities \(G_{\text{e-m}} = I_\text{m}/U_\text{e-m}\) and \(G_{\text{e-b}} = I_\text{b}/U_\text{e-b}\) (Figure 1, b).

Naturally, that current directions are not considered here and values of currents and voltages are taken by modulus. Figure 2 shows a vector field of electric intensity and field of equipotential surfaces in MWZ in a two-coordinate presentation, obtained by means of electrostatic modelling [8] in PDETool MatLab medium. The image demonstrates division of the electric current flow, passing from the electrode on two passes (conventional inner channels of MWZ) — electrode–current-supplying section of the mould and electrode-bottom plate.
At such interpreting of the inner electrical connections of the elements of surfacing working zone, the mould will be a three-terminal device. If a surfacing diagram with one power source is used, than the mould due to electrical connection of any two (of three) elements (poles) is transformed into a two-terminal device, to terminals of which the source is connected.

Conductivity of conventional «inner» channel of the working zone characterizes a physicochemical state of «channel medium». The «channel medium» is a conventional presentation of the medium, through which current passes between the corresponding inputs/outputs, i.e. current-supplying elements of the mould working zone. Current can pass through the electrode or billet, through slag, through cooled walls of the mould, deposited metal and bottom plate. Conductivity of each of mentioned components of the medium depends on temperature of corresponding parts of the electrode, zones of slag pool and many others. Operator when setting the initial parameters of surfacing such as grades of used consumables, electrode diameter, rate of its immersion into a slag pool and voltage of power source can form the channel medium and, thus, vary nature of its conductivity. At that, change of voltage, applied to the channel, does not change its conductivity in allowably long time duration till the voltage change would not lead to variation of properties of media itself. In turn, introduction into the slag pool of electrode or billet having high conductivity and temperature different from the slag temperature will result in rapid change of pool properties and, thus, change of conductivity of the channels. Thus, in some way it can be assumed that conductivity of the inner channels of the surfacing working zone are the complex parameters characterizing surfacing process in CSM.

Position of the electrode in the slag pool effects the channels’ conductivity and, if the temperature of slag is kept constant, relationship of channel conductivities can be indirectly used for estimation of location of end of the consumable electrode in the weld pool. At that, conductivities of the channels can be automatically controlled and regulated for automation purposes. Regulation of electrode feed rate on relationship of channels’ conductivity will provide a set location of end of the consumable electrode in the slag pool.

One more of the complex parameters is consumed power. A temperature mode of surfacing process is determined by consumption of power of electric energy applied to the corresponding channel, i.e. for our example \[ P_{\text{e-m}} = I_{\text{e-m}} U_{\text{e-m}} \] and \[ P_{\text{e-b}} = I_{\text{e-b}} U_{\text{e-b}}. \] Regulation of the consumed power allows controlling the temperature mode and efficiency of surfacing process. Automatic control of the consumed power of applied electric energy is possible and variation of the consumed power in both channels to the set value is achieved by change of source voltage. Maintenance of the set relationship of conductivities in both channels and set power of electric energy applied to corresponding channel provides the possibility of quality characteristics of the deposited layer and fusion zone.

Let’s consider a diagram for connection of the elements of surfacing working zone presented in Figure 1, b. If it is assumed that as a result of multiple experiments it was possible to determined the values optimum for technological purposes of conductivity and consumed power of electrode–mould channel, for example \[ \rho_{\text{e-m}} = \rho_{\text{opt}} \] and \[ \rho_{\text{e-m}} = \rho_{\text{opt}} \text{m} \], then after small transformations it is obtained \[ U_{\text{e-m}}^{\text{opt}} = \sqrt{\rho_{\text{e-m}}^{\text{opt}} / \rho_{\text{e-m}}} \]. So, operator or automatic system should have the possibility in process of surfacing to maintain \( U_{\text{e-m}}^{\text{opt}} \) value (at that, it is assumed that the electrode feed rate is kept constant at its optimum value). It follows from here that for the purpose of automatic regulation of surfacing process the power source voltage should be smoothly changed in the required limits. Besides, it is necessary to provide control and regulation of electrode displacement at stationary mould or, vice versa, mould at stable electrode, with sufficient accuracy and in the necessary range to maintain \( U_{\text{e-m}}^{\text{opt}} \) in accordance with the technological requirements.

It is supposed that for the specific set initial conditions of surfacing there is a single optimum solution on variation in time of electrode displacement rate as well as corresponding solution on change in time of source voltage (in set time interval). As a result of realizing such a solution it is possible to reach predicted quality of surfacing with the set values of deposition rate and energy efficiency. Search of indicated «optimum» solution should be preformed by a control system using automatic collection of data on each surfacing.

It is possible to formalize types of channels in the working zone following the ideas on the mould working zone. There are three types of diagrams of surfacing working zone channels in CSM (Figure 3), marked as «E», «K» and «P». They differ by location of common terminals of the working zone (common terminal corresponds to input/output, on which sum current \( I_{\text{sum}} \) is passing). In this interpretation the channel of surfacing working zone in CSM is a pass between the elements of this zone connected by resistor. Resistor conductivity is a channel conductivity.

Due to the fact that there are three current-supplying elements in the working zone, then number of variants of power source connection also makes three
since the source is connected to a pair of zone elements. There are only two variants for connection of remaining third terminal, namely to one or to another source terminal. Figure 4, as an example, shows the diagrams for connection of elements of working zone to alternating current power source. The diagrams for connection to direct current source are similar.

Thus, three variants of diagrams for connection of source to mould are proposed. The most perspective for increase of surfacing efficiency is «E» type diagram and, in less degree, «K», since the experience shows that the best melting of the electrode takes place at sufficiently high currents, passing through the electrode and mould, thus providing high process efficiency. In contrast to a diagram of type «P», which is characterized by high current passing through the bottom plate, small rate of electrode melting, but good and uniform penetration of the base metal.

Therefore, when choosing a diagram for connection of source to current-supplying elements of the working zone, it is necessary, first of all, orient on selection of type of channel diagram, i.e. on that which terminals shall be short-circuited. Geometry of the working zone of mould in many aspects determines this choice.

The following functions are taken as one being automated for the first stage of system development:

- function of selection and maintain of electric mode for formation of fusion of dissimilar metals with set relative nonuniformity of penetration and minimum average penetration depth;
- function of selection and maintain of electric mode for providing stable conditions of deposited metal solidification.

Selection of that or another electric mode is carried out by operator from the list provided by the system. The system is designed in such a way that a story of surfacing was collected and stored in computer memory. From the information in computer memory the operator can select necessary mode or develop new with further storage. After mode is selected and system launched «into operation», the system stabilizes the set parameters in a set range. The values of set parameters and range of stabilizing are not constant and being determined by selected mode.

Automation of mode of fusion formation between dissimilar metals with set relative nonuniformity of penetration and minimum average penetration depth requires stabilizing the set value of electrode deepening and set voltage of source in connection of source to CSM on diagram «P».

Automation of stable conditions for deposited metal solidification requires stabilizing the set value of conductivity of electrode-bottom plate channel and set voltage of source during connection of source to CSM on diagram «E».

Such an approach of electroslag surfacing was proposed in work [9] based on evaluation of longitudinal sections of bimetal billets.

Conceptually, the following functions and problems shall be fulfilled in development of a system for automatic control of ESS in CSM:

- control and indication of current values of rate of consumable electrode displacement, voltage of power source, surfacing currents passing through the electrode, mould and bottom plate;
- providing the devices setting the values of mode parameters, indication of set typical surfacing mode;
- control and indication of values of calculated parameters (value of electrode deepening, deposition rate, time of process etc.);
• mathematical modelling and experimental researches of dependencies of depth and uniformity of penetration on value of electrode deepening and power consume by current-supplying mould;
• automatic control of electrode displacement;
• automatic control of voltage, current and power consumed by surfacing.

Structural scheme of automation of base metal penetration during ESS in CSM is presented in Figure 5. The system consists of a block of «Input of analogue signals» designed for entry into the system of signals of surfacing voltage $U_s$ and currents $I_e$, $I_b$, $I_m$, i.e. electrode, bottom plate and mould, respectively, coming from probes located in the immediate vicinity to «Current-supplying mould». Block for «Output of analogue signals» is designed for output of the controlling signals $P_c$ — controller of output voltage of «Power source» and $P_{v.disp}$ — controller of displacement rate of consumable electrode, which influences a drive control block («DCB») of electrode displacement mechanism. «Panel of setting and control» is designed for manual entry and indication of discrete, digital, text information and automatic input of indicated information in «Control device» as well as obtaining from it the signal for indication on «Panel of setting and control» itself. «Control device» obtains the analogue signals from «Control object» and discrete signals from «Panel of setting and control», performs mathematical processing of these signals and forms the discrete signals for transfer into «Panel of setting and control» for indication as well as the controlling analogue signals for «Control object». Besides, it records a history of surfacing for unstudied types and modes of surfacing for the purpose of further processing of recorded information files and modernizing system software, forms an array of approximating regression functions for types and modes of surfacing provided in the system as well as an array of surfacing history.

At this stage the «Control device» is realized based on notebook LENOVO model IdealPad Y560 with 64-bit operating system. Input of analogue information is carried out using external ADT E14-140-M L-CARD (bus USB2), which is in particular conformable for development of portable measuring system based on notebook. It has software controlled setting of the parameters for data collection, namely amount and sequence of input channels’ inquiry, measurement range, frequency of analogue-digital transducer. An original non-standard device of own design is used as normalizing transducers of current and voltage signals.

«Manual» regulation was carried out using the indices calculated by the system. Manual mode was used to maintain a rate of electrode feed for the purpose of stabilizing the value of electrode deepening into the slag pool as well as value of power voltage.

Figure 6 presents a view of computer screen at initial setting of the ESS control system before surfacing. Parameters of entering and filtering the input signals, technological conditions of subsequent surfacing, type of diagram for connection of source to CSM etc. are set.

Figure 7 presents a view of computer screen during system operation in mode of control, regulation and registration of surfacing process. The values of source...
Conclusions

1. Developed were the main principles of design of the system for automatic regulation of base metal penetration in end face electroslag surfacing with large-section electrodes in current-supplying mould. A pilot version of computer system for automatic control of ESS in CSM was developed.

2. Based on the presentations of the mould working zone, technologist can choose among three proposed diagrams of current distribution in surfacing working zone, titled as «E», «K» and «P», which determine the process of electrode melting and value of base metal penetration.

3. Determined were the main controlled complex parameters in the system, i.e. electric conductivity of the channels and power consumed by them. Using them it is possible in indirect way to determine position of the end face of consumable electrode in the slag pool and regulate the process of electroslag surfacing varying the rates of electrode deepening and voltage of power source. It will result in providing the minimum and uniform penetration of the base metal, stabilizing the surfacing process with the set values of productivity and energy efficiency.

MODELING OF PHASE-STRUCTURE STATE AND REGULATION OF PROPERTIES OF Fe–Cr–Mn ALLOYING SYSTEM METAL DEPOSITED ON LOW-CARBON STRUCTURAL STEEL

Ya.A. CHELYYAKH and A.P. CHELYYAKH
Pryazovskyi State Technical University
7 Universitetskaya Str., 87555, Mariupol, Donetsk region, Ukraine. E-mail: chelyyakh_o_p@psu.edu

A physical-mathematical model was developed. It describes formation of a structure of deposited metal of Fe–Cr–Mn alloying system and binds its chemical composition, critical points of martensite transformation (M_s, M_f), phase-structure state and nature of their layer-by-layer variation on thickness of the deposited metal. The model allows designing and regulating chemical and phase compositions (austenite, austenite-martensite, martensite-austenite, martensite) of metal of Fe–Cr–Mn alloying system deposited on steel St3 that provides the possibility to regulate service properties of the deposited metal. Specific conditions of operation of the deposited parts require selection of phase composition of the deposited metal (content of quenching martensite and metastable austenite), level of γ→α'-transformation and acquiring of the most significant effect of strengthening in process of testing and operation. 14 Ref., 1 Table, 4 Figures.

Keywords: surfacing; flux-cored wire, metastable austenite, martensite, modeling, transformations, wear resistance

Regulation of structure and service properties of deposited metal (DM) is one the main problems in production and restoration surfacing of virtually all critical parts in different branches of industry [1–3]. This problem is in particular relevant in surfacing of high-manganese and high-chromium-manganese steels taking into account that these steels have metastable austenite structure, which can be strengthened in process of operation under dynamic mechanical loads [4–8]. Considering the fact that significant penetration of base metal and previous deposited layers can be observed in arc surfacing, chemical and phase composition as well as structure of the deposited metal will be changed in specific way from layer to layer.

The aim of present work is development of a scientific-based model of formation and regulation of phase-structure state and service properties of deposited metal of Fe–Cr–Mn alloying system depending on its composition and composition of base metal as well as parameters of technology of electric arc flux-cored wire surfacing.

A physical-mathematic model (No.1) of layer-by-layer-steplike distribution of alloying elements on the DM layers depending on a level of base metal penetration [9] was proposed. The model with some assumption supposes that content of alloying elements in the DM layers changes gradually. In multilayer surfacing composition of each layer is determined by distribution of previous and portion of its participation in formation of each next layer (N_1, N_2, N_3, ..., N_i). It is determined that any combinations of different or same portions of participation of base metal in the deposited one by layers, equal in the sum (N_1 + N_2 + N_3, ..., N_i), provide similar composition of the resulting (upper) deposited layer. Based on experimental investigations and analysis of formation of composition in each of the deposited layers there was obtained an equation for calculation of content of each of elements in i-th deposited layer at various levels of penetration:

\[ C_{e}^{DMi} = C_{e}^{0}N_{1}N_{2}N_{3}...N_{i} + C_{e}^{s}(1 - N_{1}N_{2}N_{3}...N_{i}) \] (1)

where \( C_{e}^{0} \) is the content of element in base metal; \( C_{e}^{s} \) is the set content of element.

At similar portion of the base metal and previous layers in the deposited metal, dependence (1) has the next view:

\[ C_{e}^{DMi} = C_{e}^{0}N_{i} + C_{e}^{s}(1 - N_{i}). \] (2)

Taking into account possible oxidation (burn-out loss) of alloying elements (in open arc surfacing) or addition of alloying elements from the flux into the melt, expressions (1) and (2) shall be completed with a summand \( \pm \Delta C_{e}^{f} \), characterizing contribution of flux content into the DM composition, similar to data of work [10]:

\[ C_{e}^{DMi} = C_{e}^{0}N_{1}N_{2}N_{3}...N_{i} + C_{e}^{s}(1 - N_{1}N_{2}N_{3}...N_{i}) \pm \Delta C_{e}^{f}. \] (3)

Obtained equations (1)–(4) prove the known conclusion that the less the penetration level and, respectively, portion of participation of base metal into deposited one \( N \) is, the quicker and at less amount of layers the set composition of the DM is reached [1].

At different portion of participation of the base metal in each of the deposited layers of multi-layer surfacing the result of calculation of element content is determined taking into account their product \((N_1N_2N_3 \ldots N_i)\). Based on set forth, a physical-mathematical model of layer-by-layer formation of chemical and phase composition (No. 1), graphical interpretation of which is given in Figure 1, was proposed. After first layer surfacing on unalloyed steel-base (St3) the content of alloying elements in the first DM layer is sufficiently rapidly increased at transfer of a fusion zone and on thickness of this layer the average concentration remains approximately the same, that corresponds to a horizontal section of a concentration distribution curve. At that, the set content of alloying elements in the first layer is not usually achieved. After surfacing of the second layer the concentration of alloying elements on fusion zone of the first and second layers due to penetration of the first layer with specific \( N_2 \) again rises, and, approximately, stays the same on thickness of this (second) layer (Figure 1, curves 1, 2). Composition of the third and next layers is formed in the same way.

According to calculations, content of carbon also gradually varies by layers to the side of increase, or, vice versa, reduction (as it is shown in Figure 1, curves 5, 6) depending on its content in metal-base in relation to content in flux-cored wire. In layers 4–6 the concentration of the elements will correspond to set content of the flux-cored wire.

The quicker the rate of surfacing and the less current in studied limits \((v_{surf} = 18–38 \text{ m/h}, I = 320–500 \text{ A})\) are, the less the portion of participation of metal from each previous layer in formation of the next one is, the narrower the zone of interlayer fusion is and the larger the difference in the concentrations of elements between the horizontal lines on concentration curves of a layer-by-layer analysis is.

The layer-by-layer calculation of metal deposited with flux-cored wire PP-Np-12Kh13G-12STAF, using proposed model is given in the Table. As can be seen from the given data, multilayer surfacing provides DM with the structure of metastable austenite. Relationship of the alloying elements (first of all chromium and manganese) as well as carbon, having significant effect (decrease) on points of \( M_s \) and \( M_f \) was selected in such a way that in the upper layer of DM it was austenite metastable structure, corresponding to 12Kh13G12STAF composition.

At small portion of the base metal and next layers \((N_1, N_2, N_3 \leq 0.3)\) the set composition of metal, deposited with wire PP-Np-12Kh13G-12STAF is already reached in the third layer, which corresponds to steel 12Kh13G12STAF with metastable austenite. At average values of \( N_1, N_2, N_3 \approx 0.5 \) the set composition of DM can be obtained only in the forth or even fifth layer. In the third layer it will correspond to grade 14Kh12G11STAF of austenite class with under-alloying on chromium (by \( \sim 1.5 \% \)), manganese (by \( \sim 1.5 \% \)) and overrating by 0.02 % content of carbon (Table).

At large portion of the base metal and next layer in the deposited metal \((N_1, N_2, N_3 \approx 0.7)\) the set composition of metal, deposited with wire PP-Np-12Kh13G-12STAF is already reached in the third layer, which corresponds to steel 15Kh9G8STAF (Ta-

**Note.** M — quenching martensite; A — austenite.
ble) with lack of alloying from the set composition on chromium and manganese by ~ 4 %, on silicon by ~ 0.6 %, excess of carbon content by ~ 0.03 %, content of vanadium and titanium can be at lower limits. This deposited metal refers to martensite-austenite class. In surfacing with penetration level \( N \approx 0.7 \) (modes, which provide such a penetration, are not recommended to be used in surfacing), acquiring the set composition will only be possible in layers 6–7. Reliability of the results of DM calculation on the developed model is proved by the experimental results of works [9, 10] and others.

Composition of each layer effects martensite points \( M_s, M_f, M_d \) and determines phase composition of the layers of deposited metal [11, 12]: austenite (A); austenite-martensite \((A + M)\) (< 50 % of quenching martensite and > 50 % of austenite); martensite-austenite \((M + A)\) (> 50 % of quenching martensite, the rest is \( A_{ret} \)); martensite \((M)\) with 5–15 % of \( A_{ret} \). In all cases structure of the deposited metal includes small amount of carbides (carbonitrides).

Nature of distribution of chemical elements according to the proposed model is proved by the experimental results of spectral (quantometric) analysis on quantometer «SpectromaxX» (after step-by-step grinding away of a layer by 0.3–0.5 mm as well as micro-X-ray-spectrum analysis using autolmination electron microscope «Ultra-55» (with a step of 0.1–0.2 mm order) (Figure 2). A structure-phase state on the layers of Fe–Cr–Mn DM was determined by the methods of quantitative metallography and X-ray structural analysis on diffractometer DRON-3 in iron \( K_{\alpha} \)-radiation.

A structural class of DM (layer-by-layer) was determined on quantitative relationship of quenching martensite and metastable austenite. An upper layer in three-layer surfacing using PP-Np-12Kh13G12S-TAF wire at \( N_i = 0.31–0.40 \) corresponds to grade DM 20Kh12G9STAF and \((A + M)\) class. Within the limits of each layer there are variations of content of the elements in small limits, typical for arc surfacing with flux-cored wire. At \( N_i = 0.70–0.76 \), the DM of 20Kh10G8STAF grade and \((M + A)\) class with qualitatively similar nature of alloying elements distribution is formed in the third layer.

Due to the importance of taking into account the effect of composition of each layer on phase content of the DM, the physical-mathematical model was developed, which considers effect of the main elements (Cr, Mn, Si, C) on point \( M_i \) in Fe–Cr–Mn steels. Application of this model allowed obtaining different DM compositions \((12–20)Kh(8–13)G(6–12)STAF\)

\[ M_s(Cr) = -aCr^3 + bCr^2 - cCr + d + \Delta M_s; \tag{4} \]
\[ M_s(Mn) = -a(Mn)^2 - b(Mn) + c + \Delta M_s; \tag{5} \]

where \( Cr \) and \( Mn \) is the content of elements in the DM, wt.%; \( a, b, c, d \) are the constant coefficients reflecting the level of element effect; \( \Delta M_s \) is the average value of displacement of p. \( M_i \) from the experimental dependencies under effect of carbon and alloying elements (on generalizing the reference data provided in work [12]):

\[ \Delta M_s = -500\Delta C - 38\Delta Mn - 8\Delta Cr - 40\Delta Si, \tag{6} \]

where \( \Delta C, \Delta Mn, \Delta Si, \Delta Cr \) are the difference between the content of the alloying element in the experimental and model DM, %.

The correlation coefficients made: for equation (4) — \( R^2 = 0.9999; \) (5) — \( R^2 = 0.9975. \)
A series of curves were plotted in a calculation way with the help of equations (4)–(6) using the model, namely dependencies of $p_\text{Ms}$ from content of chromium and manganese at the discrete values of content of the rest elements (Mn, Cr, Si, C, respectively), some of which are given in Figure 3. For any ratio of the main alloying elements (Cr, Mn) the temperatures of $p_\text{Ms}$ were calculated using the model and in cooling to room temperature there were determined an amount of forming phases — martensite and austenite in Fe–Cr–Mn structure of the DM. Thus, for the DM, containing approximately Cr 10 %, Mn 8 %, C 0.2 % (at similar content of silicon and vanadium), $p_\text{Ms} = 40^\circ\text{C}$ (Figure 3, $a$, curve 2). At room temperature its phase composition is ~ 82 % of austenite and ~ 18 % of quenching martensite (Figure 3, $b$, curve 2). And for steel with the same content of chromium (~ 10 %), but higher content of manganese, for example, 10 %, its structure will be austenitic. The calculated ratios of phase composition (content of martensite and austenite) are proved by the experimental data of magnetometric and X-ray structural methods, given in works [10, 12].

The developed model allows also using the set phase composition determining the necessary composition of alloying elements in the DM and corresponding to it position of $p_\text{Ms}$. Based on this content using the known methods [13] it is possible to calculate composition of the charge of flux-cored wire, which will provide formation of set chemical and phase-structure composition of the DM.

The obtained calculation ratios of amount of quenching martensite and metastable austenite for Fe–Cr–Mn of DM adequately correspond to the experimental results determined by magnetometric and X-ray structural methods [11, 12].

Generalization of two models considered above allows explaining the differences of layer-by-layer formation of DM phase content on concentration of the chemical elements according to the next cause-and-effect relationship. Chemical composition of each deposited layer depends on composition of material being deposited, level of penetration (portion) of base metal and further deposited layers (Figure 4, $a$). Content of elements in the layers determines the temperatures of $p_\text{Ms}$ and $p_\text{Mf}$ (Figure 4, $b$) effecting the amount of martensite and metastable austenite in the limits from 0 % to 100 % of each phase (Figure 4, $c$) forming during Fe–Cr–Mn DM cooling. This relationship determines formation of wear resistance of the examined DM (Figure 5). In the first approximation, the more formation of quenching martensite is, the higher the hardness and wear resistance are, and the more remaining austenite is, the lower these properties are, but higher ductility and impact toughness are. However, these characteristics and wear resistance of DM depend not only on ratio of amount of quenching martensite and austenite. Particularly important is that austenite in the structure of the examined Fe–Cr–Mn DM is a metastable phase subjected to deformation martensite $\gamma\rightarrow\alpha'$-transformation in the process of testing (wear-out) (DMTW) provoking deformation hardening and, simultaneously, stress relaxation. A level of metastability, determining DMTW kinetics and amount of forming deformation martensite, depends on different factors, namely ratio between content of quenching martensite and metastable austenite, content and level of its strengthening, heat treatment, conditions of tests and operation [8, 11]. All these in total determine formation of mechanical and service properties of the DM of Fe–Cr–Mn alloying system.

Figure 4, $b$ schematically shows a graphical dependence of $p_\text{Ms}$ position on content of one of the alloying elements in Fe–Cr–Mn DM (for example, chromium, manganese or carbon). Dependence of amount of quenching martensite $M$ and austenite $A$ on position of $p_\text{Ms}$ are given in Figure 4, $c$. The latter shows various quantitative ratio between quenching martensite for different content of the alloying
elements and, respectively, different temperature of p. Ms (for example $a_1$, $b_1$, $a_2$, $b_2$ in Figure 4, $c$).

Obtained experimentally graphical dependencies between p. Ms and amount of quenching martensite M, austenite A for system of steel alloying with 30Kh(2–14)G6S2F and 10Kh14G(0–12)content [11] are approximated by a polynomial function of the 3rd level:

$$M(\%) = -6 \cdot 10^{-5} (M_s)^3 + 0.147(M_s)^2 - 0.2236(M_s) + 0.8859;$$
$$A(\%) = 100 - M(\%).$$

At that a coefficient of correlation made $R^2 = 1.0$.

A projection of points of curve p. Ms – f(\% Cr, Mn, Si) of the model (No.2) (Figure 4, $b$) on steplike curves of the model (No.1) (Figure 4, $a$) explains the nature of alternation of the phase-structure compositions: base metal $\rightarrow$ (M + A) $\rightarrow$ (A + M) $\rightarrow$ A on its thickness (from fusion zone with base metal to surface layer), that is determined by p. Ms temperature, depending on content of alloying elements in the DM layers (Figure 4, $a$).

The generalized model allows predicting and designing the phase composition of the DM by layers taking into account technological parameters of surfacing mentioned above. Rising content of such elements as Cr, Mn, Si, C (separately or in a complex) provokes reduction of p. Ms (Figure 4, $b$) and variation of phase composition to the side of increase of austenite content, and decrease of content of quenching martensite, respectively (Figure 4, $c$). Following form the set chemical composition of DM, a series of curves p. Ms – f(\% Cr, Mn, Si) were plotted using model No.2 [12] (Figure 4, $b$, curves 1–3).

When generalizing models Nos 1 and 2 it is possible quantitatively calculate obtained phase composition (% A; % M) in each deposited layer taking into account technological parameters of surfacing mentioned above. Rising content of such elements as Cr, Mn, Si, C (separately or in a complex) provokes reduction of p. Ms (Figure 4, $b$) and variation of phase composition to the side of increase of austenite content, and decrease of content of quenching martensite, respectively (Figure 4, $c$). Following form the set chemical composition of DM, a series of curves p. Ms – f(\% Cr, Mn, Si) were plotted using model No.2 [12] (Figure 4, $b$, curves 1–3).

received points on curves 1, 2, 3 (Figure 4, b) through Figure 4, c on Figure 4, a. Projecting determined in such a way phase composition (wt.%) from curves on Figure 4, a to the curve (Figure 4, b), and from it down to Figure 4, c it is possible to get a qualitative and quantitative presentation on phase composition of each of the deposited layers (Figure 4, a).

As an example it is possible to consider the DM corresponding to curve 1 of distribution of alloying elements by layers (Figure 4, a). The first (lower) layer is characterized with a horizontal shelf of step, which shall be projected on curve 1 (Figure 4, b), corresponding to present deposited metal and conditions of surfacing, and characterizing dependence p. Mn and content of elements in this layer. The projections of obtained point on a phase composition diagram (ratios of phases of quenching martensite — M and austenite — A) show the content of quenching martensite (p. $b_2 \approx 65\%$) and austenite ($a_2 \approx 35\%$). Points $b'_2$ and $a'_2$ are characterized with martensite-austenite (M + A) phase composition of the first layer (shown by arrow to brace on Figure 4, a). The second layer is characterized by corresponding step (Figure 4, a), projection of which on Figure 4, b for considered above curve 1, and down from it to Figure 4, c show the obtained phase composition, which is characterized by points $a'_1 \approx 89\%$ of austenite and $b'_1 \approx 11\%$ of quenching martensite. The projections of these points (portion) of base metal and next layers.

In a similar way it is possible to consider formation of composition, and from it through effect on p. Ms (Figure 4, b) i.e. formation of phase composition (A and M) on Figure 4, c for other conditions of surfacing characterized by lower content of alloying elements and carbon (curve 2 on Figure 4, a) or, vice versa, large one (curve 3 in Figure 4, a). This depends on somewhat different composition of the deposited metal of the same Fe–Cr–Mn alloying system, or at its similar composition on other indices of penetration (portion) of base metal and next layers.

Obtained calculation results on content of martensite and metastable austenite on DM layers, the same as layer-by-layer-steplike nature of change of chemical phase-structure compositions on the DM layers, are proved by quantometric analysis, electron microscopy, metallographic and X-ray structural examinations.

In total, obtained in surfacing microstructure and level of $\gamma$-phase metastability determine the nature and $\gamma \rightarrow \alpha'$ kinetics of DMTW and allow regulating formation of physical-mechanical and service properties. Selecting indicated parameters, it is possible to get combinations of different phase-structure zones (A, A + M, M + A, M) of Fe–Cr–Mn deposited metal of different thickness.

Hardness and wear resistance of the DM is varied corresponding to layer-by-layer nature of change of the phase-structure state and level of deformation of austenite metastability. Schematically it is shown in Figure 5 based on generalizing the results of our previous researches [10, 11, 14], where similar curves for the DM of various chemical and phase compositions are given. The highest hardness of Fe–Cr–Mn DM corresponds to (M + A) structure (first or second layer), then it drops due to increase of content of more plastic austenite in (A + M) structure and decreases to larger level for austenite structure (the second or third layer, respectively). Following the experimental data, the highest wear resistance of the DM of Fe–Cr–Mn alloying system is provided by austenite-martensite structure with active $\gamma \rightarrow \alpha'$ kinetics of DMTW [10, 11].

The reason of significant increase of wear resistance of metastable Fe–Cr–Mn DM with (A + M) structure is obtaining in surfacing of some amount of quenching martensite (20–30%) and formation of significant amount of deformation martensite in thin surface layer (30–55%) as a result of $\gamma \rightarrow \alpha'$ development of DMTW as well as cold working of martensite-austenite structure under effect of wear-out medium.

The deformation martensite differs by increased dispersion, higher level of microdistortions and increased dislocation density, and process of its formation is accompanied by relaxation processes [8] that promotes rise of DM ductility, wear resistance and life duration. It is also probable development of dynamic deformation ageing characterized with precipitation of high-disperse par-

Figure 5. Dependence of hardness (curve) and relative wear resistance under different conditions of wear out of metastable Fe–Cr–Mn DM: 1 — metal on metal; 2 — impact-abrasive; 3 — abrasive
articles of carbides and carbonitrides from martensite and austenite in course of wear out in the surface layer that is also an important factor of wear resistance increase. Certainly, for specific conditions of operation of the deposited parts it is necessary to select phase composition (content of quenching martensite and metastable austenite), level of metastability of $\gamma$-phase providing optimum $\gamma\rightarrow\alpha'$ development of DMTW and acquiring the highest strengthening effect in the process of tests and operation.

In whole, the optimum parameters of chemical and phase composition, microstructure and $\gamma\rightarrow\alpha'$ kinetics of DMTW for each type of wear out provide improved characteristics of properties and wear resistance of the examined metastable DM, which significantly exceed properties of deformation-stable materials of close alloying.

VISIT TO WELDING CENTER OF ISF-2 PROJECT IN CHERNOBYL

Today interest to nuclear safety is relevant like never before. For Ukraine it is, first of all, connected with large-scale accident at Chernobyl NPP in 1986. By the initiative of the journal editorial board in July, 2018 there was organized a visit to ISF-2 facility of specialists of the E.O. Paton Electric Welding Institute in the lead of deputy director Prof. L.M. Lobanov.

Currently, works on project ISF-2 are carried out in Ukraine in order to solve the problem of safe storage of spent nuclear fuel as well as materials from ruined by accident 4th power generating unit of ChNPP. The project is held under the supervision of the International Atomic Energy Agency and agreements of SSE Chernobyl NPP with Holtec International Company, USA.

A course of work performance in Ukraine on ISF-2 project is carried out under the supervision of government, State Nuclear Regulatory Inspectorate of Ukraine and according to the project of Holtec International Company. Participation of the E.O. Paton Electric Welding Institute in the separate stages of ISF-2 construction at Chernobyl NPP is determined by the project.

It is supposed that at the end of 2018 there will be carried out the «hot» tests at new ISF-2 facility, which includes an object on preparation of spent nuclear fuel and storage itself (Figure 2). Start of work in full capacity is planned for fourth quarter of 2019. Launching the new storage is rated as substantial forward step of Ukraine in development of facility, operation of which will allow changing the existing scheme of handling the spent nuclear fuel of domestic nuclear power plants, thus, strengthening energy security. It is planned that the facility will provide safe storage of the spent nuclear fuel from Rivne, Khmelnytskyi and South-Ukraine NPP for 100 years. Operation of the facility will be carried out using advanced technology of «dry» storage with two-barrier sealing system, which is provided with the help of special engineering systems of canister type from Holtec International Company. The latter are double-wall dry canisters (DWC) of around 4 m length and 2 m diameter.

Today DWCs of American production are delivered to ISF-2. It should be noted that SSE ChNPP is ready to consider the proposals of the Ukrainian enterprises on organization of production of such canisters using domestic materials.

Loading of spent nuclear fuel in DWC, welding of two main lids and welding-up of three auxiliary ports in the lids (Figures 3, 4) will be provided during ISF-2 operation. Automatic nonconsumable electrode welding with feeding of «hot» filler metal (welding

Figure 1. Object for SNF preparation
of the lids) and manual TIG (auxiliary ports) will be used for welding operations by Holtec International technology.

A welder-operator will carry out a remote control of the process of automatic multipass welding of the lids in the specially equipped site having the possibility of visual monitoring of the process and regulation of weld metal formation. For performance of this process Holtec has selected the arc equipment (power source and welding automatic machine with wire heating) of well-known company Liburdi (Figure 5).

E.O. Paton Electric Welding Institute carries out separate operations of technological processes of welding (under conditions of ChNPP exclusion zone) of seal welds on DWC loaded with spent nuclear fuel under the contract with Holtec International Company. They include:

- elaboration of version of Holtec technological instructions for welding of seal welds;
- preparation of welding process flow-charts of each weld, their qualification and agreement with SNRIU applicable to working conditions in SSE ChNPP exclusion zone;
- qualification of welding technological process at SSE ChNPP production facility for performance of welding of seal welds on DWC loaded with spent nuclear fuel;
- training and qualification of welder-performers of DWC seal welds under conditions of ChNPP exclusion zone;
- participation in control field test of welding technological process of seal welds on DWC loaded with spent nuclear fuel;
- compiling the analytical scientific-technical reference-substantiation for granting SSE ChNPP with a license from SNRIU for performance of works on DWC sealing.

Currently, old storage contains 21297 spent fuel elements, which will be transferred to ISF-2. Every year it is planned to move 2500 fuel assemblies, i.e. in a 10-years period all the nuclear wastes will be located in ISF-2, period of storage of which is around 100 years.
